- Typically a 90-degree adolescent AO blade plate is used for fixation. If no varus or valgus deformity correction is required, the guidewire for chisel placement is placed at a 90-degree angle to the femoral shaft on an AP image in the plane of the tibia (as this will reflect final coronal plane alignment) (TECH FIG 1A).
- The guidewire entry point is through the anterior portion of the lateral femoral epicondyle in line with the femoral shaft to avoid anterior or posterior translation of the distal fragment. It is placed just proximal to the distal femoral physis if the patient is immature and at the physeal scar if growth is complete.
- Transverse-plane position is in line with the axis from the lateral to the medial femoral condyle.
- The chisel is inserted exactly parallel and just proximal to the pin, with the angle guide for the AO chisel aligned parallel to the tibia (TECH FIG 1B). The angle between the AO chisel guide and the femoral shaft is equal to the degree of knee contracture and the extension to be obtained.

- Depending on preoperative assessment, a second pin can be placed proximal to the osteotomy site to assist with rotational control. It can be placed at a converging angle in the transverse plane to match the degree of derotation desired.
- The distal osteotomy is performed first. The oscillating saw blade is aligned exactly parallel and 10 to 15 mm proximal to the chisel (TECH FIG 1C).
- The second osteotomy is performed perpendicular to the femoral shaft, typically meeting the first osteotomy at the posterior cortex (although with more severe deformities, a cuneiform wedge including several millimeters of posterior cortex may also be removed to avoid neurovascular stretch).
- The anterior wedge of bone is removed (TECH FIG 1D).
- Varus–valgus deformities can be corrected by altering the guide pin placement in the coronal plane or bending the implant to match the desired correction.
- The osteotomy is realigned by derotating if necessary and extending the knee.
- The chisel is replaced with the Synthes AO blade plate.
- The femoral shaft is reduced to the plate and held with a Verbrugge clamp (TECH FIG 1E).
- After an initial screw is placed in compression to hold alignment, final coronal plane alignment is assessed. Proper mechanical axis alignment is confirmed if the elec-
If the patient is skeletally immature, transposition of a tibial tubercle bone block would cause an anterior growth arrest. Instead, the patellar tendon is advanced without violating its insertion (**TECH FIG 2A**).

A T-shaped periosteal incision is made just distal to the tibial tubercle apophysis.

Medial and lateral flaps of periosteum are elevated (**TECH FIG 2B**).

The tendon is separated from the cartilaginous tibial tubercle apophysis using a fresh scalpel, working at the junction of the fibers of the patellar tendon and the cartilage (**TECH FIG 2C**). It is best to err on the side of leaving a few fibers of tendon on the cartilage than to inadvertently injure the cartilage. Care must be taken to maintain an adequate thickness of tendon (about 2 mm) without defects.

The next step is placement of a tension band from the patella to the tibia to protect the repair. A guidewire for the 2.7-mm cannulated AO drill bit is passed percutaneously transversely through the midportion of the patella.

A suture passer is passed retrograde through the drill bit from medial to lateral, and then the drill bit is removed. A 2-mm Fibertape suture is passed through the drill hole using the suture passer.

Using a long right-angle clamp, the ends of the Fibertape suture are passed along the edges of the patellar tendon via a subcutaneous tunnel to the anterior incision.

Using a similar technique as described for the patella, a transverse drill hole is placed in the tibia and the suture is passed through it (**TECH FIG 2D**).

The patella is advanced distally by tensioning the Fibertape until the inferior pole of the patella is at the femoral–tibial joint line, at which point the knot in the Fibertape is tied (**TECH FIG 2E**).

Two baseball (Krackow) stitches are placed in the patellar tendon, one medially and one laterally, using 0 Ethibond suture (**TECH FIG 2F**).

These sutures are tied deeply under the periosteal flaps.

The periosteal flaps are then sewn over the patellar tendon (**TECH FIG 2G**).

The wound is closed in routine fashion.
TIBIAL TUBERCLE ADVANCEMENT

- For skeletally mature patients, the patellar tendon and tibial tubercle are exposed.
- A small tibial tubercle bone block with patellar tendon attached is created with an oscillating saw and completed with an osteotome. The typical size is the width of the patellar tendon, 2 to 2.5 cm in length and 7 to 10 mm thick.
- The 2-mm Fibertape is placed identical to the previous description.
- A receptacle site for the tibial tubercle bone block is created at the appropriate level.
- The distally excised bone block is impacted into the original tibial tubercle site.
- The tibial tubercle is inserted into its receptacle site and secured with a single 4.5-mm AO screw, overdrilling the tibial tubercle fragment to compress the bone block and countersinking to avoid screw prominence.
- The typical advancement is 2 to 2.5 cm.
- By keeping the tibial tubercle bone block relatively short in length, a small bridge of intact anterior cortical bone can provide a proximal buttress to resist proximal migration of the tibial tubercle bone block postoperatively.
- The knee should be able to flex 60 degrees at this point without excessive tension or disruption of the repair.
- The wound is closed in routine fashion.

PEARLS AND PITFALLS

| Recurrence of knee flexion deformity and persistence of crouch | If a distal femoral extension osteotomy is performed without patellar advancement, there is a high risk of these postoperative problems. |
| Patellar advancement in isolation | This is effective to treat crouch in the presence of a knee extension lag without knee flexion contracture. |
| Avoiding sciatic nerve palsy | Postoperative immobilization in flexion during the time of acute swelling (first 3 days) and resection of the posterior bony prominence on the distal fragment have helped minimize this complication. |
| Loss of patellar fixation | Supporting patellar advancements with a Fibertape tension band has minimized this complication. |
| Increased anterior pelvic tilt | Detecting and treating hip flexion deformity as well as rectus femoris spasticity and contracture (simultaneous rectus femoris transfer) have been helpful, but this finding seems to be common with surgical intervention at this age. |
| Genu varum and valgum | Distal femoral osteotomy requires meticulous care to ensure optimal postoperative alignment in all three planes. |
| | Contractures between 10 and 25 degrees are typically appropriate for this compensatory osteotomy of the distal femur. |
| | In growing children with relatively small deformities, anterior distal femoral figure 8 plating may be a consideration. |
| | The treatment of flexion contractures of 30 degrees or greater introduces significant distal femoral deformity. |
| | Modest transverse-plane deformities can easily be corrected but again this requires meticulous attention to detail. |
| | Malrotation greater than 30 degrees is difficult to correct with this technique. |
| | Preoperative coronal-plane deformities can be corrected, and care must be taken to avoid creation of postoperative varus–valgus deformities. |

POSTOPERATIVE CARE

- AP and lateral radiographs are reviewed to confirm proper alignment (FIG 3).
- The knee is immobilized for 3 days in 20 to 30 degrees of flexion in a Robert Jones dressing to avoid sciatic nerve stretch.
- Then a knee immobilizer is used for 6 weeks.
- Use of a continuous passive motion (CPM) machine is begun on the third postoperative day; initially the range is from 0 to 30 degrees, and it is advanced to 90 degrees by 6 weeks postoperatively.
- After 3 weeks, active range of motion and weight bearing are initiated. Once quadriceps strength and control are sufficient, the knee immobilizer can be discontinued.

OUTCOMES

- Knee flexion deformity and patella alta can reliably be corrected.4
- Preoperative stress fractures and knee pain are improved or resolved in the vast majority of patients.
- Worsened anterior pelvic tilt is commonly seen and does not seem to be a result of persisting contracture or weakness.
- Crouch gait is corrected effectively for those who have the combined procedure of extension osteotomy and patellar advancement. Crouch is also effectively treated in the absence of knee contracture with patellar advancement alone, as long as other musculotendinous contractures and bone or joint deformities are concurrently addressed.
Distal femoral extension osteotomy without patellar advancement has a high risk of recurrence of contracture and typically results in only partial improvement in crouch.

- An overcorrection of patellar position compensates for weakness, impaired motor control, and spasticity and has been found to be safe (low rate of persisting anterior knee pain postoperatively) and necessary to treat crouch.
- The natural history of crouch gait is one of worsening. With these procedures, walking ability is either maintained or improved, as indicated by gait analysis and a functional mobility scale.  

**COMPLICATIONS**

- Sciatic nerve palsy
- Loss of patellar fixation
- Recurrence of deformity
- Wound breakdown or infection
- Increased anterior pelvic tilt

**REFERENCES**

DEFINITION

- **Unicameral bone cyst (UBC)**
  - Also known as a simple bone cyst, a UBC is a benign, active or latent, solitary cystic lesion that usually involves the metaphysis of long bones (most commonly the proximal humerus and femur, 40% to 80%).
  - Most (90%) of patients are less than 20 years old.
  - UBCs represent a cavity filled with yellowish or serosanguineous fluid lined by a thin fibrous membrane.

- **Aneurysmal bone cyst (ABC)**
  - ABC is a benign, active, and sometimes locally aggressive, solitary, expansile cystic lesion, eccentric in location.
  - ABCs are most common in the first two decades, and they most often involve the long bones or the spine.
  - The lesion contains blood-filled cystic spaces that are not lined with vascular endothelium. Between the blood-filled spaces are fibrous septa containing giant cells and immature bone.

PATHOGENESIS

- **UBC**
  - Cause is unknown; however, theories range from a reactive or developmental process, caused by obstruction to the drainage of interstitial fluid, to a true neoplasm.
  - Recent isolated cytogenetic analysis has reported on the presence of translocation t(16;20)(p11.2;q13) and TP53 mutations in recurrent UBCs. Further studies are necessary to better understand its pathogenesis.
  - UBCs are characterized by a fluid-filled cyst lined with a thin fibrous membrane without obvious lining cells. However, owing to the high incidence of associated fractures, several nonspecific changes may be seen, such as hemorrhage, hemosiderin deposits, granulation tissue, new bone formation, and others.

- **ABC**
  - The neoplastic basis of primary ABCs has been, at least in part, demonstrated by the chromosomal translocation t(16;17)(q22;p13) that places the ubiquitin protease (UBP) USP6 gene under the regulatory influence of the highly active osteoblast cadherin 11 gene (CDH11), which is strongly expressed in bones.
  - ABCs are characterized by various-size blood-filled cystic spaces without vascular endothelium lining and divided by fibrous septa containing giant cells and immature bone (**FIG 1**).

NATURAL HISTORY

- **UBC**
  - Active cysts are generally located near the growth plate and are usually asymptomatic.
  - Inactive or latent cysts tend to “migrate” away from the growth plate as longitudinal growth occurs.
  - UBCs may regress spontaneously after skeletal maturity.

- **ABC**
  - It is usually an active benign lesion with locally aggressive features.
  - The lesion tends to continue to grow, necessitating intervention.
  - It can occur as a secondary lesion associated with giant cell tumor, osteoblastoma, chondroblastoma, or fibrous dysplasia.

PATIENT HISTORY AND PHYSICAL FINDINGS

- **UBC**
  - UBCs are often asymptomatic. The usual presentation is with a pathologic fracture (50% to 65%).

**FIG 1** • High-power (200× magnification; A) and low-power (40× magnification; B) photomicrographs of a lesion demonstrate blood-filled spaces surrounded by several focal giant cells, as well as spindle-shaped cells lining the walls of these spaces. Some of the spaces are slit-like, whereas the other spaces are dilated. Hemosiderin is also seen.
While about 90% occur before the age of 20 years, calcaneal UBCs tend to occur in a slightly older group. They occur more often in boys (3:1). The most common locations are the proximal humerus and femur, accounting for 50% to 70% of the lesions.

ABCs often present with mild pain. Pathologic fracture is not uncommon, following minor trauma. The spine, femur, and tibia are the most common locations. In the spine, the lesion is more often limited to the posterior elements.

IMAGING AND OTHER DIAGNOSTIC STUDIES

UBC
- Plain radiographs typically demonstrate a centrally located, well-defined, radiolucent lesion (Fig 2), usually surrounded by a sclerotic margin and narrow zone of transition.
- They may demonstrate cortical thinning and mild expansion (unlike ABCs, UBCs do not exceed the width of the nearest growth plate).
- When a pathologic fracture occurs, there is periosteal reaction, and occasionally the typical “fallen fragment” sign is visualized (piece of fractured cortex “floating” inside the cavity).

CT is usually useful to characterize lesions that are difficult to visualize on plain films (ie, spine, pelvis) and to rule out fractures (nondisplaced or minimally displaced).

MRI is useful for differential diagnosis and atypical UBCs. Although variable, they present as low to intermediate signals on T1-weighted images and bright and homogeneous signals on T2-weighted images.

ABC
- Plain radiographs show an eccentrically located, multilobulated, expansile (expands beyond the width of the nearest growth plate), radiolucent lesion with a narrow zone of transition.
- A rim of sclerotic bone is often seen.
- Cortical thinning, disruption, and periosteal reaction are common.
- CT is helpful, especially because these lesions are commonly located in the spine (Fig 3A,B).
- It shows the typical ridges in the interior of the cyst.
- Soft tissue extension can be appreciated, but there is no true soft tissue mass.
- MRI is useful to confirm the lobulated nature of the lesion and the cystic cavities filled with fluid (fluid–fluid levels on T2-weighted signal; characteristic but not pathognomonic; Fig 3C,D).
- There is variable signal intensity in both T1- and T2-weighted images due to the nature of the cyst contents (fresh blood, mixed with degraded blood products).

DIFFERENTIAL DIAGNOSIS

UBC
- Nonossifying fibroma
- Fibrous dysplasia
- Brown tumor of hyperparathyroidism (usually presents with osteopenia and subcortical resorption)
- Bone abscess (commonly shows periosteal reaction).
- For calcaneal lesions, the differential also includes chondroblastoma and giant cell tumor.

ABC
- Latent UBC (diaphyseal)
- Fibrous dysplasia
- ABC
- UBC
- Giant cell tumor

FIG 2 • Lateral radiograph of the foot of a 12-year-old boy demonstrates a well-circumscribed, lucent lesion, consistent with unicameral bone cyst.

FIG 3 • Aneurysmal bone cyst of L4. A. Axial CT scan of the lower lumbar spine shows a destructive, lytic, expansile lesion, involving the body and posterior elements of L4 with disruption of the spinal canal. B. Three-dimensional-reconstruction CT image demonstrates the asymmetric collapse of the vertebra. C. Sagittal T1 MRI shows the collapsed L4 with posterior disruption by the tumoral mass. D. Axial T2-weighted MRI shows the characteristic fluid-fluid level and disruption of the medullary canal.
- Osteoblastoma
- Telangiectatic osteogenic sarcoma

**NONOPERATIVE MANAGEMENT**

### UBC
- Lesions with typical radiographic appearance and lesions in non-weight-bearing bones can be followed with serial radiographs.
- Small lesions (i.e., those that involve less than one third to half of the bone width) in weight-bearing bones that have low risk for fracture can also be observed.
- Following pathologic fracture, up to 14% of UBCs may spontaneously heal, and therefore an attempt for conservative treatment should be made.

### ABC
- There is little place for conservative treatment of ABCs. At least an incisional biopsy for diagnosis confirmation is recommended.
- For small, asymptomatic lesions located in non-weight-bearing bones, observation can be indicated.

**SURGICAL MANAGEMENT**

- The first indication for surgical treatment of benign bone cysts is to confirm the diagnosis (i.e., incisional biopsy).
- Large lesions that involve more than one third to half of the bone width and lesions of weight-bearing bones are usually treated with surgery.
- Pathologic fractures are not an absolute indication for surgical treatment, but when they are associated with ABCs, or are located in the lower extremities, surgery is usually indicated.

### ABCs in nonessential bones (e.g., rib, fibula) can be treated with wide resection to avoid recurrence.

**Preoperative Planning**

- It is very important to pay attention to the details, formulate the differential diagnosis, and rule out a malignant process. It is also very important to rule out physial growth arrest before any intervention.
- For ABCs, an open biopsy is often needed since needle biopsy may get only blood and no tissue.
- An image intensifier is useful for accurate localization of the lesion, during percutaneous procedures, and for intraoperative confirmation that the entire lesion is being addressed.
- For open surgery, headlamps for illumination and loupes for magnification are recommended.

**Positioning**

- Positioning depends on the lesion’s location. For all extremity lesions, the entire affected extremity should be entirely free draped. It is important to confirm that the extremity can be properly imaged by the image intensifier.

**Approach**

- UBCs are less aggressive lesions and therefore are prone to a percutaneous technique.
- ABCs can be quite aggressive and an open and more aggressive approach is usually necessary.
- For lesions in the proximal femur, a more aggressive approach is often necessary; particularly if a pathologic fracture is present, open reduction and internal fixation is indicated (FIG 4).

---

**FIG 4** • Classification and treatment algorithm for proximal femur pathologic fractures through a bone cyst. Type IA: A small cyst is present in the middle of the femoral neck, the lateral buttress is intact, cannulated screws are used avoiding the physis. Type IB: A larger cyst is present, there is compromise of the lateral buttress, and a pediatric dynamic hip screw (DHS) is used. Types IIA and IIB: There is not enough bone between the growth plate and the lesion; therefore, the patient can be kept in traction or a cast until initial healing occurs, or parallel Steinmann pins across the physis can be used. Type IIIA: Since the growth plate is closed, cannulated screws purchasing the femoral head are used. Type IIIB: Because of the loss of the lateral buttress, a pediatric DHS is recommended. A spica cast is generally recommended after the surgical treatment. Internal fixation should be preceded by a four-step approach. (Adapted from Dormans J, Flynn J. Pathologic fractures associated with tumors and unique conditions of the musculoskeletal system. In Beaty JH, Kasser JR, eds. Rockwood and Wilkins’ Fractures in Children, ed 5. Philadelphia: Lippincott Williams & Wilkins, 2001:151.)
UNICAMERAL BONE CYST

Percutaneous Intramedullary Decompression, Curettage, and Grafting With Medical-Grade Calcium Sulfate Pellets

- Under fluoroscopic guidance, a Jamshidi trocar needle (CardinalHealth, Dublin, OH) is percutaneously inserted into the cyst cavity.
- The cyst is aspirated to confirm the presence of straw-colored fluid, which is typical of previously untreated or unfractured UBCs.
- Three to 10 mL of Renografin dye (E.R. Squibb, Princeton, NJ) is injected to perform a cystogram and confirm the single fluid-filled cavity (TECH FIG 1A).
- A 0.5-cm longitudinal incision is then made over the site of the aspiration and a 6-mm arthroscopy trocar is advanced into the cyst cavity through the same cortical hole, and the cortical entry is enlarged manually (TECH FIG 1B).
- Under fluoroscopic guidance, percutaneous removal of the cyst lining is done and curettage is performed using a pituitary rongeur and various-sized angled curettes (TECH FIG 1C).
- An angled curette or flexible intramedullary nail is used to perform the intramedullary decompression in one direction (toward the diaphysis) or in both directions (when the growth plate is far enough, avoid physeal injury) (TECH FIG 1D,E).
- Medical-grade calcium sulfate pellets (Osteoset, Wright Medical Technology, Arlington, TN) are inserted through the same cortical hole and deployed to completely fill the cavity (TECH FIG 1F,G).
- Angled curettes can be used to advance pellets into the medullary canal.
- Tight packing of the cyst is preferred.
- The wound is closed in a layered fashion.

TECH FIG 1 • Unicameral bone cyst. A. Fluoroscopic image showing a proximal femur unicameral bone cyst filling with dye. B. A 0.5-cm incision is made where the Jamshidi needle for the cystogram was placed. C. The cyst is curetted using curettes and a pituitary rongeur. Material is then sent for pathology analysis. Intramedullary decompression of the cyst is done using flexible intramedullary nails (D) or angled curettes (E). F. The cyst is filled with medical-grade calcium sulfate pellets. G. Four-month follow-up radiograph shows complete healing.
ANEURYSMAL BONE CYST

- A four-step open surgical approach is used.
- Under fluoroscopic guidance, a Jamshidi trocar needle is percutaneously inserted into the cyst cavity.
- The cyst is aspirated to confirm the presence of blood-filled cavities or soft tissue septations typical of ABCs.
- A longitudinal incision of roughly the same size of the cyst is made, the neurovascular structures are protected, and the periosteum is opened and retracted.
- Perforation of the thinnest part of the cyst wall is performed with a curette, burr, or drill.
- The fibrous lining of the lesion is completely curetted. Septations are opened and removed to access all components of the cyst.
- The use of headlamps for illumination and loupes for magnification is recommended to ensure a thorough excision. Image intensifier may be helpful to ensure that all cavities were opened.
- A high-speed burr is used to improve the curettage and help with complete excision of any macroscopic tumor (TECH FIG 2A,B).
- The cavity is then cauterized with electrocautery and in selected cases (eg, lesions distant from the growth plate and main neurovascular structures) phenol 5% solution is applied to the cyst wall with a cotton-tipped applicator to extend the margins.
- The cavity is now tightly packed with bone graft. We prefer to use a combination of allograft cubes and demineralized bone matrix paste (TECH FIG 2C–F).
- The wound is closed in a layered fashion.

**TECH FIG 2** • **A.** AP radiograph of the proximal humerus shows an expansile, lytic, loculated aneurysmal bone cyst. **B.** The cyst is thoroughly curetted and a high-speed burr is used to remove any residual cyst lining. **C.** The cyst is completely filled with packed allograft chips and demineralized bone matrix. **D.** Radiographic aspect 2 weeks after the procedure; the cyst was entirely removed and the cavity was entirely grafted. **E,F.** At 4-month follow-up, AP radiographs of the right proximal humerus in internal and external rotation demonstrate that the lesion is completely healed, with good incorporation of the bone graft.
POSTOPERATIVE CARE

- In most cases, the extremity is protected from weight bearing for about 4 to 6 weeks. Before the patient is allowed to return to physical activity, radiographic evidence of bone healing is necessary.

OUTCOMES

- The minimally invasive technique for UBC has shown promising results on a short-term evaluation, with reported success rate (eg, complete or partial healing or opacification) of about 95%. Recently the intermediate to long-term results in a larger cohort were reviewed, and the observed rate of complete or partial response achieved with one surgical intervention was 80%. Nonetheless, the success rate increased to 94% after a repeat surgery, reaching a 100% healing rate in patients who underwent more than two repeat surgeries. These results compare favorably with other outcomes after surgical treatment of UBCs.
- The recurrence rate for any surgically treated ABC varies from 10% to 59% according to the reported results. In a large cohort including 45 children with primary ABC treated by the described four-step approach technique and at least 2 years of follow-up, the recurrence rate was only 18%. Although the recurrence rate was slightly higher among younger children (less than 10 years old), this difference did not show statistical significance.

COMPLICATIONS

- Persistence or recurrence: varies from 10% to 20% for all techniques described
- Infection
- Fracture
- Intraoperative bleeding: for aggressive-looking ABCs and lesions in difficult locations such as the pelvis and spine, arteriography, and sometimes embolization, is helpful.

REFERENCES

DEFINITION

- **Syndactyly** refers to the failure of separation between adjacent digits, resulting in “webbed” fingers.
- Congenital syndactyly is classified according to the extent of digital involvement and the character of the conjoined tissue.
  - *Complete syndactyly* extends to the digital tips (FIG 1A), whereas *incomplete syndactyly* ends proximal to the fingertips (FIG 1B).
  - *Simple syndactyly* refers to digits connected only by skin and soft tissue. *Complex syndactyly* denotes bony fusions between adjacent phalanges.
  - *Complicated syndactyly* refers to the interposition of accessory phalanges or abnormal bones between digits.

ANATOMY

- Understanding of normal digital web space anatomy guides surgical reconstructive efforts.
- Typically, the index–long and ring–small finger commissures are U-shaped, whereas the long–ring web is V-shaped.
- The non-glabrous skin of the normal web space is sloped about 45 degrees from proximal–dorsal to distal–volar, extending to roughly the midpoint of the proximal phalanx.
- The natatory ligaments (or superficial transverse metacarpal ligament) help form the web contour and join adjacent lateral digital sheets.
- Normally, each digit is vascularized in part via a radial and an ulnar digital artery, which arise from the bifurcation of the common digital arteries.
  - In simple syndactyly, adjacent digits are joined by varying amounts of skin and soft tissue.
    - The nail plates may or may not be fused.
    - The joints, ligaments, and tendons of the affected digits usually are normal.
  - It is of critical surgical importance that the bifurcation of the digital arteries and nerves may be abnormally distal in cases of syndactyly.

PATHOGENESIS

- Syndactyly represents a failure of differentiation and is so classified by the embryologic classification of congenital anomalies adopted by the International Federation for Societies for Surgery of the Hand.
  - Embryologically, the digits arise from condensations of mesoderm within the rudimentary hand paddle of the developing upper limb.
  - During the 5th and 6th weeks of gestation, interdigital clefts form through the process of apoptosis, or programmed cell death, beginning at the digital tips and proceeding in a distal-to-proximal direction.
  - The apical ectodermal ridge regulates this embryologic process, in conjunction with fibroblast growth factors, bone morphogenetic proteins, transforming growth factors, homeobox gene products, and the sonic hedgehog protein.
- Interruption of this precise and highly regulated process results in syndactyly.

NATURAL HISTORY

- There is no potential for spontaneous resolution.
- Given the importance of independent digit function in today’s world, surgical release is recommended for simple complete syndactyly, with few exceptions.
- When digits of differing lengths are joined, the syndactyly may lead to deformity and growth disturbance, with the longer digit typically developing a flexion contracture and angular deviation toward the shorter digit.
- Simple complete syndactyly of the long–ring interspace may be well tolerated and may not significantly compromise growth or function in young patients.
- Simple incomplete syndactylies may be aesthetically subtle and cause little functional compromise. In these situations, observation may be considered.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The diagnosis of syndactyly usually is not subtle, and the extent of digital involvement typically is readily apparent.
- Syndactyly is the most common congenital hand anomaly, with an estimated incidence of 1 in 2000 to 2500 live births.
  - The true incidence of syndactyly is unknown, in part because of the difficulty distinguishing mild simple syndactylies from normal web spaces.
The third web space is most commonly affected (50%), followed by the fourth (30%), second (15%), and first (5%) web spaces.

Males tend to be more commonly affected than females, and whites more than blacks or Asians.

Inheritance is thought to be autosomal dominant with incomplete penetrance and variable expression.

The absence of differential motion of the affected digits suggests a complex or complicated syndactyly.

Because the joints and tendons usually are normal, patients typically have flexion and extension creases over the interphalangeal joints and active digital motion.

Syndactyly may exist in isolation or may be seen in the context of associated clinical syndromes, including Poland syndrome, Apert syndrome, and constriction band syndrome. For this reason, careful evaluation of the entire upper extremity, contralateral upper limb, chest, and feet is advised.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Plain radiographs of the affected digits or hand are routinely obtained to accurately classify the syndactyly and assess for bony fusions or interposed or accessory bones (FIG 2).
- MRI, angiography, or other diagnostic studies are not typically obtained, because they do not assist surgical decision-making or operative treatment.

**NONOPERATIVE MANAGEMENT**

- Nonoperative management may be considered for mild, simple incomplete syndactyly.
- Nonoperative treatment also may be favored in cases of complicated syndactyly with the so-called “superdigit” or in cases of complex polysyndactyly, because of the difficulty in achieving reproducible functional improvement with surgical release.
- However, given the importance of independent digital motion—particularly in the current keyboard-driven digital age—nonoperative treatment of simple complete syndactyly is not recommended.

**SURGICAL MANAGEMENT**

- General surgical principles include the following:
  -Digits of differing lengths should be released early to prevent deformity and growth disturbance of the affected digits.
  -Digits should be operated upon on only one side at the same time, to avoid vascular embarrassment.

  - Local skin flaps should be used to recreate the commissure to avoid scar contracture and “web creep.”
  - Zigzag lateral flaps should be created to avoid longitudinal scar contracture.
  - Judicious defatting of the skin flaps should be performed to facilitate skin closure, reduce tension across the flaps, and improve the aesthetics of the reconstructed fingers.
  - Full-thickness skin grafts typically are used to cover “bare areas” after syndactyly release. (In cases of simple complete syndactyly, the combined circumference of the separated digits is 22% greater than the original circumference of the syndactylized digits.)

**Preoperative Planning**

- The timing of surgery must be considered in preoperative planning.
- There is great variability in recommendations of when releases should be performed.
  - Flatt wrote, “I believe one should ask not how soon the operation can be done but rather how late the functional demands of the hand will allow postponement of surgery.”
  - In general, releases are performed between 6 and 24 months of age.
- As mentioned, digits of differing lengths (eg, thumb–index syndactyly) should be released earlier to avoid secondary deformity.
- There is some evidence that releases performed after 18 months have better long-term outcomes with lower incidence of web creep.

**Positioning**

- The patient is positioned supine with the affected limb supported on a hand table.
- Placement of a sterile or nonsterile tourniquet must be sufficiently proximal to allow access to the antecubital fossa, if full-thickness skin graft is to be taken from that site.
- If the skin graft is to be harvested from the inguinal region, the ipsilateral groin is prepared and draped to allow for easy access.
- Before draping, a surgical pen may be used to mark the inguinal skin fold when the hip is flexed; graft harvest along this axis will allow for a more aesthetic skin closure.
- Care should be taken to harvest the skin graft lateral to the femoral artery to avoid transfer of hair-bearing skin.

**Approach**

- The principles of separation for simple complete syndactyly are well accepted; however, there is tremendous variation in the surgical incisions and skin flap designs used for these operations.
- All use local tissue to reconstruct the interdigital commissure, and all employ interdigitating zigzag lateral flaps. Dorsal skin flaps are preferred for commissure reconstruction, because of their pliability and ability to recreate the normal dorsal–proximal to volar–distal slope of the web.
- When dorsal skin is used to create the commissure, the length of the dorsal flap should approximate two thirds of the length of the proximal phalanx to create an appropriate slope to the web. The proximal extent of the volar incision will become the new palmodigital crease (FIG 3A).
- Furthermore, flaps are designed to interdigitate during closure; to achieve this, palmar triangular flaps are based at the level corresponding to the apex of the dorsal flaps. These flaps usually are fashioned to traverse between the midlines of the syndactylized digits.
- **FIGURE 3B** shows examples of skin incisions for simple complete syndactyly releases.
RELEASE OF SIMPLE SYNDACTYLY

Release of Simple Complete Syndactyly Using Full-Thickness Skin Graft

- After the tourniquet is inflated, the skin is incised, and hemostasis achieved with bipolar electrocautery (TECH FIG 1A,B).
- Dorsal skin flaps are raised first, preserving the extensor paratenon.
- Volar skin flaps are then raised, and neurovascular bundles are identified.
- Digits are carefully separated distal-to-proximal, releasing the interdigital fascia that often connects the syndactylized digits (TECH FIG 1C). The transverse metacarpal ligament is not divided.
- The bifurcation of the common digital artery and nerve is identified; if there is a distal bifurcation precluding restoration of the commissure with the dorsal skin flap, consideration may be given to splitting the fascicles of the common digital nerve or ligating one of the proper digital arteries.
- For isolated syndactyly release, the smaller-caliber or nondominant artery may be taken.

- If a syndactyly release is planned on the other side of one of the digits, its proper digital artery should be preserved.
- Skin flaps are then defatted and allowed to interdigitate.
- The dorsal skin flap is then advanced to the palmodigital crease and secured with multiple interrupted 5-0 absorbable sutures (eg, chromic or polyglactin; TECH FIG 1D).
- Interdigitated skin flaps are similarly reapproximated with multiple interrupted 5-0 absorbable suture.
- Skin defects are identified and covered with full-thickness skin graft, which may be harvested from the hypothenar eminence, antecubital fossa, or inguinal region (TECH FIG 1E).
- The tourniquet is deflated, and vascularity of the digits and flaps is confirmed.
- A non-adherent gauze bolstered with moist cotton is then placed into the newly formed web space, applying gentle compression to the skin graft sites.
- Care should be taken to place the dressing deep within the commissure to avoid re-syndactylization during the healing process.

TECH FIG 1 • Dorsal (A) and volar (B) incisions for planned release of simple complete syndactyly of the long and ring fingers. C. The digits have been separated. D. The dorsal skin flap is sewn in to recreate the interdigital commissure. E. Completion of the release with full-thickness skin grafting. (Copyright 2006 Children’s Orthopaedic Surgery Foundation.)
An above-elbow cast is then applied with the elbow in 90 degrees of flexion, with liberal use of casting material to protect the surgical dressing.

Reconstruction of the Paronychium

In cases of simple complete syndactyly, the nail plates of the involved digits are conjoined, a phenomenon known as synonychia.

Although division of the midportion of the nail plate is easily performed, care must be made to reconstitute the nail folds.
- Ideally this is performed using local tissue from the digital pulp.²
- Laterally based flaps are incorporated into the skin incisions, raised from the shared hyponychium at the digital tips (TECH FIG 2).
- The length of the flaps should equal the length of the nail plate.
- Once these flaps are raised and the digits separated, the flaps are easily rotated and reapproximated adjacent to the new nail plates, recreating a paronychial fold.
- Alternative solutions, including the use of skin graft, thenar or hypothenar flaps, or free composite toe grafts, are more involved and may provide less pleasing aesthetic results.

Technique of “Graftless” Syndactyly Release

Simple complete syndactyly releases may also be performed without the need for full-thickness skin grafting.⁵,¹³

In general, principles of syndactyly release mentioned earlier apply.

In “graftless” techniques, however, dorsal skin is raised from the dorsum of the hand and advanced to recreate the interdigital commissure. The resulting defect is closed primarily in the fashion of a V-Y advancement flap (TECH FIG 3).

Because proximal skin is used to recreate the web, more tissue is available to allow for primary closure of the digits following judicious defatting of the flaps, obviating the need for skin grafting.

The use of preoperative tissue expansion to avoid the need for skin grafting for syndactyly release has been proposed. Results have been unpredictable at best, however, and this approach currently is not widely accepted.

Local Skin Flaps for Simple Incomplete Syndactyly

In cases of simple incomplete syndactyly in which the web does not extend beyond the level of the proximal interphalangeal joint (ie, the length of the syndactyly does not exceed the desired depth of the reconstructed interdigital commissure), release may be performed using local skin flaps without the need for full-thickness skin grafting.

Multiple flap designs have been proposed, and, in general, all are variations of double opposing Z-plasties¹⁴,¹⁶ (TECH FIG 4).

In these situations, brief postoperative cast immobilization is recommended until skin flaps have healed.
POSTOPERATIVE CARE

- Cast immobilization usually is discontinued after 2 to 4 weeks.
- The wound is kept dry until the scabs desiccate and fall off.
- Silicone gel sheets, elastomere, or scar molds may be used to minimize hypertrophic scar formation.
- Formal occupational therapy for motion and strengthening is not typically required, because most children will use their hands quite readily with activities of daily living.

OUTCOMES

- Very little has been published regarding long-term outcomes following surgical release of syndactyly.
- Furthermore, interpretation of the available literature is difficult given the diversity of clinical presentations, surgical techniques, and methods of evaluation.
- In general, syndactyly release can be expected to provide excellent independent digital function with acceptable aesthetic results when performed according to the principles outlined in this chapter.
- Colville\(^1\) reported the results of 57 simple syndactyly releases performed over a 10-year period with minimum 2-year follow-up.
- Two patients required reoperation for early graft failure, and three others demonstrated slight angular deformity due to scar contracture, but they did not require additional surgery.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Category</th>

</tbody>
</table>
D’Arcangelo et al. published their results of 122 releases in 50 patients with minimum 8 years of follow-up. Satisfactory functional and aesthetic results were seen in most patients, but eight patients demonstrated web creep and three patients developed scar contractures. DeSmet et al. reported their results of 50 syndactyly releases in 24 patients. A normal or near-normal web was seen in 74% of cases, and cosmesis was deemed satisfactory in 64%. In their review of 218 releases performed in 100 patients, Percival and Sykes noted that 42 patients required secondary surgery for web creep (22%) and contracture (26%). Toledo and Ger published their results of 176 releases performed in 61 patients with average 14-year follow-up. Secondary procedures were performed in 30% of patients with simple syndactylies. The need for secondary surgery was associated with operations performed before the age of 18 months, the use of split-thickness skin grafts, and the presence of complex or complicated syndactyly.

COMPLICATIONS
With adherence to the principles presented in this chapter and meticulous surgical technique, the risk of complications may be minimized; however, up to one third of patients may require secondary procedures following simple complete syndactyly release. Digital necrosis is the most serious potential complication of syndactyly release. Careful identification and preservation of the digital arteries—in addition to avoidance of surgical release of both the radial and ulnar sides of a single digit at the same time—is critical to avoid vascular embarrassment and digital loss. Skin graft failure may result from hematoma formation beneath the graft or shear stresses imposed on the graft during the healing process. This risk may be greater in younger patients, in whom appropriate graft tensioning is more difficult and in whom postoperative immobilization is a greater challenge. If allowed to heal by secondary intention, subsequent hypertrophic scar formation may lead to suboptimal aesthetic and functional results. Skin flap failure due to devascularization is less common but also may lead to scarring and secondary contracture. Triangular skin flaps should be designed with tip angles greater than 45 degrees to prevent tip necrosis. Careful defatting of the flaps and primary closure without excess tension, in addition to assessment of flap viability after tourniquet release, will further aid in preventing skin flap complications. Contractures and angular deformity of the released digits may occur owing to linear scars on the radial or ulnar aspects of the fingers. Use of zigzag incisions and interdigitating flap designs will minimize this risk. Nail plate deformity is common after simple complete syndactyly release in the presence of a synonychia.

Although techniques of nailfold reconstruction using distal pulp tissue will optimize aesthetic results, patients and families should be counseled in advance regarding this common occurrence. “Web creep” refers to the distal migration of the reconstructed interdigital commissure with continued growth and is a common occurrence following syndactyly release, with a variously reported incidence of between 7% and 60% of cases. Some evidence suggests that the risk of web creep may be diminished if release is performed after 18 months of age. Other factors that may contribute to web creep include inappropriate flap design for commissure reconstruction, the use of split-thickness rather than full-thickness skin grafts, skin graft loss, and creation of a transverse linear scar in the reconstructed web space. In cases of clinically significant web creep, secondary releases may be required.

REFERENCES
DEFINITION
- The thumb-in-palm deformity is a fixed adduction–flexion posture in the affected hand of the patient with spastic cerebral palsy. This influences both hand function and hygiene.

ANATOMY
- Imbalance of the spastic thumb flexor–adductor and the paretic thumb extensor results in thumb-in-palm deformity (FIG 1A).
- The adductor pollicis (AP) is the most commonly involved muscle; the abductor pollicis brevis (APB) is usually not involved.\(^1\)
- The spastic AP, the first dorsal interosseous muscle, or both adduct the thumb and index metacarpals and cause first web space contracture.
- If the flexor pollicis brevis (FPB) is spastic, the thumb metacarpophalangeal (MCP) joint will develop a flexion deformity.
- Involvement of both the AP and FPB results in a thumb flexion and adduction posture with the thumb lying across the palm.
- Involvement of the flexor pollicis longus (FPL) results in added thumb interphalangeal (IP) joint flexion (FIG 1B).
- Weak thumb extensor and abductor pollicis longus (APL) may also contribute to the deformity.

PATHOGENESIS
- Upper motor neuron lesions due to antenatal cerebral infaracts, kernicterus, intraventricular bleeding, head trauma, anoxia, and other causes result in spasticity, which in turn causes shortening of the myotendinous unit and secondary contractures.
- Paresis of muscles may contribute to greater deformity when spastic muscles are unopposed.

NATURAL HISTORY
- A supple thumb-in-palm posture is a normal finding in infants during the first year. Persistence of a tightly closed thumb in palm longer than 1 year is abnormal and should be evaluated.
- The deformity is usually correctable at first and then progresses to a fixed deformity as myostatic contracture develops.
- A progressive and variable-size discrepancy of the involved limb may develop, resulting in a smaller thumb.\(^1\)
- The lack of thumb extension and abduction can impair hand grip, function, appearance, and hygiene.

PATIENT HISTORY AND PHYSICAL FINDINGS
- A complete history and physical examination of a child with cerebral palsy should be done carefully and thoroughly.
- Input from other professionals such as neurologists and occupational therapists is often helpful.
- Repeated observation or videotaping of the child during various activities can also be useful for accurate evaluation.
- The diagnosis and pattern of cerebral palsy should be confirmed before planning treatment.
- Associated deformities of the spastic upper extremity such as finger and wrist flexion, forearm pronation, elbow flexion, and shoulder adduction and internal rotation should also be evaluated. Surgical treatment of thumb-in-palm deformity may be only one part of surgical care of the involved extremity.
- Thumb muscle involvement, motion, and stability should be evaluated in the physical examination before organizing the treatment plan.
- Individual muscle involvement is detected by observing thumb position and palpating spastic or contracted muscles (Table 1).
- Motion and stability are assessed by passive and active range of thumb abduction-adduction, flexion–extension, and palmar abduction and opposition.
- The pattern of voluntary grasp and release of large objects and manipulation of small objects should be determined by observing the child during functional activities.
- Sensory deficits impair function. Assessment of sensation should include stereognosis.
DIFFERENTIAL DIAGNOSIS
- Clasped thumb
- Distal arthrogryposis
- Absence of thumb extensor (faux extensor agenesis)

NONOPERATIVE MANAGEMENT
- Use of tone-reducing medication such as botulinum toxin to the adductor pollicis can soften the deformities and improve joint range of motion for nonoperative management.
- In mild deformity, nonoperative treatment with orthoses may help in maintaining thumb abduction, but too-rigid splinting may result in limited thumb motion.

Positioning

The patient is placed in the supine position, and surgery is performed under general anesthesia and tourniquet control.

Approach

Surgical approaches for thumb-in-palm deformity depend on the objectives.

Release of static or longstanding intrinsic contracture is usually performed through a curved incision located over the line of the thenar crease to release the origin of the adductor pollicis with or without the origin of the FPB.

Release of a simple intrinsic contracture may be performed through the first web space approach to release the adductor pollicis and the first dorsal interosseous muscle, combined with four-flap or double-opposing Z-plasty to release the secondary web space contracture.

A surgical approach by a small incision over the volar aspect of the distal forearm is used for extrinsic release of the FPL tendon, if necessary.

A dorsal approach to the thumb and a dorsoradial approach over the wrist is used for augmentation of thumb extensors, with a volar-radial approach being used for augmentation of the thumb abductor.
RELEASE OF CONTRACTURES

Release of Static Intrinsic Contracture
- A curved skin incision is performed next to the line of the thenar crease, extending distally from the carpal tunnel area (TECH FIG 1A).
- The superficial palmar arch and median nerve, including its motor branch to the thenar muscle, distal to the transverse carpal ligament are identified and protected. Careful dissection must be performed because occasionally the motor branch comes through the transverse carpal ligament instead of being distal to this structure (TECH FIG 1B).
- The flexor digitorum sublimis and profundi are identified and retracted ulnarly with the neurovascular bundle.
- The transverse head of adductor pollicis is identified and divided from its origin on the third metacarpal (TECH FIG 1C,D).
- The motor branch of the ulnar nerve and the deep palmar arch are identified and protected.
- Release of the oblique head of the adductor pollicis from its origin at the bases of the second and third metacarpal, capitate, and trapezoid is performed.
- The FPB origin at the transverse carpal ligament and trapezium may also be released if this muscle limits abduction and extension of the thumb ray.
- The first dorsal interosseous may be released at the distal portion of the muscle from the ulnar aspect of the first metacarpal if needed to obtain adequate passive abduction and extension of the thumb.

Release of Simple Intrinsic Contracture
- A four-flap Z-plasty over the contracted first web space is designed (TECH FIG 2A,B).
- After the skin incision, the dorsal fascia is incised while protecting the neurovascular bundles.
- The first dorsal interosseous is released at its origin from the thumb metacarpal.
- The adductor pollicis is lengthened by release in an oblique cut at its intramuscular tendon; the surgeon should aim to preserve some adductor function (TECH FIG 2C).
- Four skin flaps are rearranged to increase the first web space (TECH FIG 2D).

Release of Extrinsic Contracture
- A small longitudinal incision over the distal-volar aspect of the forearm is performed.
- The FPL tendon is exposed and incised over the musculotendinous portion.
- The thumb interphalangeal joint is hyperextended until 1 cm of distal sliding of the FPL tendon is identified.
- The FPL may be lengthened by Z-lengthening of the FPL tendon, with 0.5 mm of lengthening for each degree of correction.1

TECH FIG 1 • Intrinsic release. A. A curved incision is made over the thenar crease. B. Thenar release showing motor branch. C,D. Thumb intrinsics are released.
AUGMENTATION OF WEAK MUSCLES

Abductor Pollicis Longus Augmentation

- Two small transverse incisions over the volar wrist crease and the first extensor compartment are made, aiming to expose the palmaris longus (PL) or flexor carpi radialis (FCR) and APL, respectively.
- The superficial branch of the radial nerve is identified and protected.
- The first extensor compartment is then opened, and the APL is identified. Each slip of the APL tendon should be pulled into tension to show the best slip for carpometacarpal joint abduction.
- At the volar incision, the palmar branch of the median nerve is identified and protected. The PL tendon is then divided.
- The selected APL tendon slip is translocated volarly until acceptable thumb metacarpal abduction is achieved.
- The PL tendon is passed through a subcutaneous tunnel to the volar-radial incision.
- End-to-side tendon weave of the PL to the translocated APL is then performed under sufficient tension to obtain appropriate thumb abduction (TECH FIG 3A).
- Alternatively, the APL tendon may be cut and the distal segment rerouted volarly and woven with end-to-end PL or end-to-side FCR. The proximal segment of the APL may be used to augment thumb MCP joint extension by end-to-side anastomosis with the EPB (TECH FIG 3B).
**Extensor Pollicis Longus Rerouting**

- A dorsal skin incision over the thumb MCP and IP joint and another small longitudinal incision just ulnar to the Lister tubercle are used for this procedure. The EPL tendon is identified and divided 10 mm distal to the MCP joint. The tendon is then retracted out to the second incision (TECH FIG 4A).
- The MCP joint is set in 10 degrees of flexion, 10 degrees of abduction, and slight pronation,9 and a small (1 mm in diameter), smooth Kirschner wire is passed through the joint centrally to minimize epiphyseal damage (TECH FIG 4C).

**STABILIZATION OF THUMB METACARPOPHALANGEAL JOINT**

**Thumb Metacarpophalangeal Joint Arthrodesis**

- A dorsoulnar incision is made over the thumb MCP joint. The extensor mechanism is split longitudinally, and the ulnar collateral ligament is then detached from the metacarpal head to expose the joint (TECH FIG 5A).
- The articular cartilage of the metacarpal head is removed with a scalpel and the proximal phalanx epiphysis is shaved until the secondary center of ossification is exposed (TECH FIG 5B). This allows fusion of the epiphyses and preserves the physis.
- The joint is set in 10 degrees of flexion, 10 degrees of abduction, and slight pronation, and a small (1 mm in diameter), smooth Kirschner wire is passed through the joint centrally to minimize epiphyseal damage (TECH FIG 5C).
**Sesamoid Capsulodesis**

- A curved dorsoradial incision is made over the thumb MCP joint.\(^\text{11}\)
- The accessory collateral ligament is divided at its insertion into the volar plate.
- The volar plate is then mobilized to expose the radial sesamoid.
- The articular cartilage of the sesamoid is denuded. A cortical defect is created at the head–neck junction of the metacarpal.

- The suture is passed through the sesamoid–volar plate and metacarpal defect with straight needles by using a Kirschner wire driver (**TECH FIG 6A**).
- The MCP joint is set to 30 degrees of flexion. The intrasosseous suture is then tied over the dorsal surface of the metacarpal under the extensor tendons to secure the sesamoid to the metacarpal neck.
- A Kirschner wire is passed through the joint to maintain the joint position for 6 weeks (**TECH FIG 6B**).
POSTOPERATIVE CARE

- Postoperative care for contracture releases includes immobilization in a short-arm thumb spica cast maintaining full thumb radial abduction and 20 degrees of palmar abduction for 4 weeks.
- Removable splinting is then continued for another 4 to 6 weeks.
- If tendon transfer has been done, immobilization should be extended to 6 weeks, followed by additional splinting for 6 weeks. Dynamic splinting may be considered.
- Immobilization of the MCP arthrodesis with a thumb spica cast should be continued until radiographic healing is detected.

OUTCOMES

- The functional outcome of thumb-in-palm deformity should be assessed before and after surgery by the physician, therapist, parent, and patient.
- House et al\(^2\) demonstrated improved functional grade in all 56 patients postoperatively. Half of patients improved three or more grades.
- Tonkin et al\(^{12}\) found good results in 32 patients after surgical correction of thumb-in-palm deformity. The average follow-up was 32 months (range, 10 to 88 months).
  - The thumb was maintained out of palm in 29 of 32 patients (30 of 33 thumbs).
  - Patients could perform lateral pinch in 26 of 33 thumbs.
  - Many patients improved function, but no patient improved from dependent to independent functioning.

COMPLICATIONS

- Inadequate release of contracted or fibrotic muscle may result in insufficient release of the thumb out of the palm.
- Adhesions along the transferred tendon may cause loss of excursion postoperatively.
- Improper techniques such as overlengthening and an incorrect vector of transfer may result in limited active abduction and extension of the thumb.

UNTREATED OR INADEQUATE TREATMENT OF AN UNSTABLE MCP JOINT MAY RESULT IN FAILED TENDON TRANSFER.

AVOIDING NEUROVASCULAR INJURY IS CRUCIAL. CARE SHOULD BE TAKEN TO PROPERLY IDENTIFY AND PROTECT NEUROVASCULAR BUNDLES THROUGHOUT SURGERY.

AN IMPROPER REHABILITATION PROGRAM AND SOCIAL SUPPORT MAY RESULT IN FAILED TREATMENT.

REFERENCES

DEFINITION

- Pediatric trigger thumb is a condition in which tightness of the first annular (A1) pulley of the thumb and an enlargement or nodule of the flexor pollicis longus tendon interact to prevent normal thumb interphalangeal joint motion.

- This condition appears distinct from pediatric trigger fingers and from adult trigger digits, although similarities in pathoanatomy and presentation have earned it its name. The term “congenital trigger thumb” is a misnomer, as it has yet to be detected at birth in several large series prospectively examining a combined 14,581 newborns in three countries.  

ANATOMY

- The flexor pollicis longus tendon courses through a flexor sheath in the thumb composed of a series of pulleys that prevent bowstringing of the tendon during thumb flexion.

- The most proximal pulley is termed the A1 pulley, given its transverse annular nature. Division of this pulley does not cause bowstringing of the tendon during thumb flexion. The next pulley is the oblique pulley, although some authors have described an intervening distinct second annular pulley analogous to the A2 pulley in the fingers. These pulleys are important constraints against bowstringing.

- The digital nerves to the thumb are in proximity to the flexor pollicis longus tendon sheath. The radial digital nerve obliquely crosses the tendon sheath just proximal to the A1 pulley, and the ulnar digital nerve runs parallel to the tendon immediately alongside the A1 pulley. Injury to these structures is possible during surgical release of the A1 pulley, so knowledge of the precise anatomy is important.

PATHOGENESIS

- The pathogenesis of pediatric trigger thumb is unknown.

- In adults, the pathogenesis of trigger digits has a predominantly inflammatory nature. However, in pediatric trigger thumb, biopsies have been unable to detect signs of inflammation by gross morphology or light or electron microscopy. 

- A genetic predisposition has been considered, especially in cases of bilateral trigger thumb, but a genetic cause for the condition is not established.  

- Traumatic etiologies have been proposed, but with no clear data to support this theory.

NATURAL HISTORY

- The natural history of pediatric trigger thumb has been a focus of recent attention. The earliest reports of the condition described spontaneous resolution as rare, but newer reports have described spontaneous improvement rates of 24% to 63%.  

- The most recent study regarding the natural history of pediatric trigger thumb reported a 63% resolution rate, although the definition of resolution was improvement in passive interphalangeal joint extension to neutral, not to the normal hyperextension. Furthermore, the average time to reach this improvement was 48 months from diagnosis. Therefore, when considering the use of observation to treat a pediatric trigger thumb, the clinician should inform the parents that the thumb motion will improve but not return to normal, and that such improvement will take an average of 4 years.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Children typically present from late infancy through 5 years of age with painless loss of motion at the interphalangeal joint. The “triggering” phenomenon that so commonly occurs in adults is rare in children.

- Parents will usually be unable to determine how long the condition has been present. Some parents will describe a preceding traumatic injury to the thumb, although such an injury may simply call the parents’ attention to the thumb closely enough to notice a pre-existing trigger thumb.

- Functional impairment and pain are unusual complaints, except in the case of active triggering.

- The typical physical examination finding is a flexion contracture of the thumb interphalangeal joint, as the nodule in the flexor pollicis longus tendon typically lies proximal to the A1 pulley, preventing distal excursion of the tendon and extension of the interphalangeal joint (FIG 1A).

- In a few cases, the nodule lies distal to the A1 pulley and the thumb rests in an extended position with the child unable to actively flex the interphalangeal joint. In this case, the passive flexion of the interphalangeal joint is normal, but interphalangeal joint flexion will not occur by tenodesis with wrist extension.

- In even fewer cases, the child will be able to actively “trigger” the thumb with active flexion and passive extension.

- Regardless of the position of the thumb interphalangeal joint, a nodule is easily palpable (and even visible) in the flexor pollicis longus tendon in the region of the palmar digital crease (FIG 1B). The nodule can be felt to move proximally and distally with even the few available degrees of movement of the interphalangeal joint.

- In longstanding cases of fixed flexion deformity, thumb metacarpophalangeal joint hyperextension laxity is common. In other cases, a coronal plane deformity resembling clinodactyly may be present, although a causative relationship has yet to be established.

- Because of the possibility of bilateral involvement, both thumbs should be examined.

- An upper limb neurologic examination should be performed, including an assessment of tone in the intrinsic muscles of the hand, since the thumb-in-palm deformity of cerebral palsy can be confused with trigger thumb.
Chapter 47  RELEASE OF THE A1 PULLEY TO CORRECT CONGENITAL TRIGGER THUMB

Pediatric trigger thumb should not be confused with congenital clasped thumb, in which the metacarpophalangeal joint is fixed in a flexed position, with normal interphalangeal joint motion (FIG 1C,D).

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Radiographs are unnecessary in the clinically obvious case; if obtained, they only confirm the resting position of the thumb interphalangeal joint.

If the examination reveals signs of trauma (eg, swelling, ecchymosis), radiographs should be considered to rule out underlying skeletal injury.

Advanced imaging is unnecessary.

**DIFFERENTIAL DIAGNOSIS**

- Congenital clasped thumb
- Thumb-in-palm deformity (cerebral palsy)
- Arthrogryposis
- Thumb hypoplasia

**NONOPERATIVE MANAGEMENT**

Nonoperative management of pediatric trigger thumb has been described, including simple observation, daily stretching by parents, splinting, and casting.

Watanabe and colleagues reported the results in 58 patients of passive stretching performed by the patient’s mother 10 to 20 times daily for an average of 44 months. Despite claiming a 96% “satisfactory result,” the authors describe only 25% of patients with locked flexion deformities experiencing improvement, and none recovering normal interphalangeal joint hyperextension. Thus, it is unclear whether their results differ from other reports of natural history, even after years of stretching exercises.

Lee and associates reported their results of splinting for passively correctable trigger thumbs (no locked flexion or extension deformities), finding a greater chance of improvement (decreased frequency of triggering) with splinting than with simple observation. Others have reported improvement in triggering with nighttime splint treatment averaging 10 months, but in a series that included trigger fingers, there was a 24% drop-out rate and there was no control group.

The role of conservative treatment of pediatric trigger thumb remains controversial. It is unclear whether conservative treatment affects the natural history and whether conservative treatment is useful for children who present with a fixed flexion posture at the interphalangeal joint (most cases).

Nonetheless, it is clear from the available data that conservative treatment offers a chance of improvement only after many months to years of daily exercises or splint use, and recovery of truly normal interphalangeal joint motion is uncommon.

Percutaneous needle release of the A1 pulley as an office procedure under local anesthesia has been described for pediatric trigger thumb, but with lower success rates than open surgical release; reported complications include incomplete release and patient intolerance of the procedure.

**SURGICAL MANAGEMENT**

Surgical release of the A1 pulley has long been recognized as a safe and effective treatment for pediatric trigger thumb.

When forming surgical indications, the surgeon must consider the available data regarding the natural history and the outcomes of conservative treatment outlined above and must discuss the options with the family. Nearly all reports of surgical treatment of trigger thumb describe complete resolution of the condition in the immediate postoperative period with a low complication rate, making surgical treatment an attractive option.

The timing of surgery is controversial. Most authors recommend delaying surgery until 1 year of age; some recommend delaying surgery until after 3 or even 5 years of age; and others just recommend an undefined period of observation before surgery. No study has shown a clear detrimental effect of delaying surgery until 3 years or later, although compensatory metacarpophalangeal joint hyperextension laxity, permanent capsular contracture of the interphalangeal joint, and coronal plane deformity of the thumb have been cited as reasons to operate before 3 years of age.

**Preoperative Planning**

Little preoperative planning is required other than preparing the child medically for the surgery and anesthesia and preparing the family for the surgery and early postoperative recovery period.

**FIG 1**

A. A typical pediatric trigger thumb locked in flexion. Note the inability to passively extend the interphalangeal joint.

B. A typical trigger thumb locked in flexion. Note the visibly protruding nodule in the flexor pollicis longus tendon at the level of the palmar digital crease.

C–D. Congenital clasped thumb. C. The flexed resting posture of both the interphalangeal and metacarpophalangeal joints. D. The interphalangeal joint typically has full passive range of motion, while the metacarpophalangeal joint is fixed in flexion, differentiating congenital clasped thumb from pediatric trigger thumb.
Positioning
- The patient is positioned supine on the operating table with the affected arm (or arms) extended on a hand table or armboard.
- A pneumatic tourniquet is placed about the upper arm. The entire limb distal to the tourniquet is prepared and draped.
- The limb is exsanguinated with an Esmarch bandage and the tourniquet is inflated to 200 mm Hg.

Approach
- The approach to the A1 pulley is best performed through a transverse incision in or immediately parallel to the palmar digital crease. Longitudinal incisions can cause loss of metacarpophalangeal joint mobility by scar contracture long term.13
- As mentioned previously, great care must be taken in the volar approach to prevent injury to the digital nerves that lie in proximity to the A1 pulley.

EXPOSURE
- A 7- to 10-mm transverse incision is planned in the region of the palmar digital crease. The exact location of the incision depends on the location of the A1 pulley relative to the crease. In the thumb with a fixed flexion posture, the proximal edge of the A1 pulley is immediately distal to the location of the palpable nodule when the interphalangeal joint is maximally extended.
- The incision need not be in the interphalangeal crease to heal with an almost imperceptible scar.
- Care must be taken to plan the incision directly over the thumb flexor sheath, which is pronated relative to the plane of the palm (TECH FIG 1A).
- The incision is made after exsanguination and tourniquet inflation. Great care must be taken to avoid incising the immediately adjacent digital nerves.
- The subcutaneous tissue is then spread bluntly to reveal the A1 pulley. The digital nerves need not be routinely dissected, as long as the transverse fibers of the pulley are very clearly visualized under loupe magnification (TECH FIG 1B).

OPEN RELEASE OF THE A1 PULLEY
- The distal and proximal edges of the A1 pulley are identified and the A1 pulley is sharply incised longitudinally along its entire length (TECH FIG 2A). The oblique pulley is identified and protected distally. A gentle spread with a blunt scissor or hemostat in the proximal aspect of the sheath entering the thenar eminence will disrupt any remaining fibrous bands that can be a source of recurrent triggering.
- The initial incision in the A1 pulley will produce an elliptical window in the pulley that may allow full extension of the interphalangeal joint (TECH FIG 2B), but the digit will still trigger postoperatively unless the entire pulley is divided.
- After adequate release, the distal edge of the A1 pulley should be separated by several millimeters, with the entire width of the flexor pollicis longus tendon clearly visible (TECH FIG 2C).
- After adequate release, the thumb interphalangeal joint should have full range of motion (TECH FIG 2D). In longstanding cases, that range of motion may not be much beyond neutral.
- If the thumb was locked in an extended position before tendon release, complete release can be confirmed by fully extending the wrist and compressing the distal volar forearm to provide proximal traction on the flexor pollicis longus tendon.
- If the thumb does not have full flexion of the interphalangeal joint with these maneuvers, the release is incomplete.
**TECH FIG 2 • (continued)**

B. Appearance of the A1 pulley after incomplete release. Note the elliptical cut edges of the pulley and the full extension of the interphalangeal joint. The intact proximal and distal ends of the pulley will be sources of recurrent triggering unless the entire pulley is released. C. Complete release of the A1 pulley. The flexor pollicis longus tendon is visible across its entire width. The forceps are holding one cut edge of the pulley. D. Full passive extension of the interphalangeal joint immediately after A1 pulley release of the patient in Figure 1A.

**CLOSURE AND DRESSING**

- The wound is irrigated and closed with simple absorbable sutures.
- The wound is infiltrated with long-acting local anesthetic without epinephrine for postoperative analgesia.
- The wound is covered by a sterile dressing and several layers of bandage and tape to prevent the child from removing the bandage (TECH FIG 3).

**TECH FIG 3 •** Postoperative dressing for trigger thumb release. Loosely wrapped gauze (A) is covered by a loosely wrapped elastic bandage (B) and a doubled-back stockinette (C) with ample tape. The multiple layers prevent premature removal by the patient. Great care must be taken to keep the dressing loose to prevent excessive swelling or even ischemia distally.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Indications</th>
<th>Given the recent literature regarding natural history and possible spontaneous improvement, parents must be made aware of the option of observation before recommending surgery, even if surgery can safely and effectively restore normal motion much faster and more reliably with very low risk.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Anesthesia</td>
<td>Because of the close proximity of the digital nerves to the flexor sheath, the patient must be able to remain still during the entire procedure. Thus, while in experienced hands the entire procedure takes fewer than 5 minutes, general anesthesia or sedation is required, administered by an anesthesiologist.</td>
</tr>
<tr>
<td>Incision placement</td>
<td>The thumb is pronated relative to the plane of the hand when the hand and thumb are held flat, making it easy to make the skin incision too radial with respect to the flexor sheath when the hand is held in this position for the surgery. Therefore, it is helpful to have an assistant hold the thumb in a vertical position to allow easier centering of the incision over the flexor sheath.</td>
</tr>
<tr>
<td>Incomplete release</td>
<td>Cases of recurrence of triggering after surgical release have been attributed to incomplete release. After complete release at the distal end of the A1 pulley, the cut ends should be pointing palmarly and not toward each other. Proximally, fibrous bands in the thenar muscles can cause persistent triggering and can be divided by a gentle spread with a blunt scissor or hemostat in the flexor sheath after A1 pulley division.</td>
</tr>
<tr>
<td>Digital nerves</td>
<td>The digital nerves need not be dissected and individually identified as long as the incision is well placed directly over the A1 pulley and subcutaneous dissection clearly reveals the A1 pulley with no overlying tissue.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- Cast or splint immobilization is not necessary postoperatively. However, protecting the incision for 7 days allows less inflamed wound healing and gives the absorbable sutures time to dissolve before the inquisitive toddler is allowed access to them.
- A multilayer dressing of gauze, tape, elastic bandage, tape, stockinette, and tape is reliable and well tolerated.
- Dressings are removed at 7 days. If a determined child manages to escape the dressing prematurely, an adhesive bandage is used in its place until postoperative day 7.
- No activity restrictions are imposed postoperatively, other than routine wound care.
- Postoperative analgesic medication beyond a single appropriate dose of acetaminophen is typically unnecessary.
- Outpatient postoperative follow-up is scheduled for 1 to 2 weeks after the surgery. Full active range of motion and function of the thumb are typically achieved within 1 to 2 weeks of dressing removal. If parents perceive hesitance to use the thumb beyond that time period, a brief course of pediatric occupational therapy may be helpful.

OUTCOMES

- Outcomes of open surgical release of trigger thumbs are excellent. Recovery of full range of motion is reported in all patients in many series.
- Series that report less than 100% surgical cure describe recurrence due to incomplete pulley release as the most common reason for unsatisfactory outcome. In these series, however, success rates exceed 93%, with 100% success after reoperation of the cases with incomplete release.
- Recovery of full range of motion after surgical correction is generally immediate. In longstanding cases, full hyperextension of the interphalangeal joint may take months to achieve despite achieving neutral extension immediately postoperatively. This phenomenon may represent a volar plate or capsular contracture of the interphalangeal joint from a prolonged locked flexion posture.
- A recent study of the long-term results of surgical treatment shows that despite obtaining normal motion postoperatively, 23% of patients followed an average of 15 years postoperatively have mild loss of interphalangeal joint motion.

COMPLICATIONS

- Although rare, recurrence of the flexion posturing or triggering is the most commonly reported complication; it is attributed to incomplete pulley release. Careful attention to surgical technique prevents this complication. If recurrence occurs, revision of the surgery with complete pulley release is curative.
- Longitudinal incisions are associated with scar contracture and patient complaints long term.
- Digital nerve injuries are exceedingly rare and unreported in all series reviewed here.
- Superficial wound infection has been reported but is generally easily treated with oral antibiotics.

REFERENCES

Cerebral palsy is a primary central nervous system dysfunction that leads to significant functional impairment owing to its secondary peripheral manifestations in the upper extremity.

- The upper motor neuron lesion in the brain leads to loss of normal inhibition of tone (ie, spasticity), loss of motor control in the limb (ie, weakness), or impaired coordination of muscle activity (ie, athetosis).
- The most common manifestation is spasticity.
- Spastic hemiplegia is the main type of cerebral palsy for which upper extremity surgery is indicated.
- In spastic hemiplegia due to cerebral palsy, the most common peripheral manifestations in the upper limb are shoulder internal rotation, elbow flexion, forearm pronation, wrist flexion and ulnar deviation, finger clenching or swan-necking, and thumb-in-palm deformity.
- Increased muscle spasticity causes muscle imbalance across joints, which leads to impaired function and over time can lead to joint contractures with skeletal deformation.
- The wrist is the most commonly affected joint and will be the focus of this chapter.

ANATOMY

- Five primary wrist motors control wrist joint position.
- The three wrist extensor muscles are the extensor carpi radialis brevis (ECRB), the extensor carpi radialis longus (ECRL), and the extensor carpi ulnaris muscles (ECU).
- The two wrist flexor muscles are the flexor carpi radialis (FCR) and the flexor carpi ulnaris (FCU).
- The finger and thumb flexor muscles (flexor digitorum profundus [FDP], flexor digitorum superficialis [FDS], and flexor pollicis longus [FPL]) cross the wrist joint and exert a wrist flexion force. The finger and thumb extensor muscles (extensor pollicis longus [EPL], extensor indicis proprius [EIP], extensor digitorum communis [EDC], and extensor digiti quinti [EDQ]) also cross the wrist joint and exert a wrist extension force.
- Each of the muscles that crosses the wrist joint exerts a vector force for wrist extension and flexion, as well as radial and ulnar deviation. These vector force graphs can be used to help determine which muscles are the major deforming force for wrist flexion posturing.
- In cerebral palsy, the most common deformity is wrist flexion associated with ulnar deviation.
  - The muscle with the greatest flexion and ulnar deviation vector is the FCU.
  - The FCU is most commonly the deforming force, particularly because it may be coupled with a weak wrist extensor–radial deviator (ECRL and ECRB).

PATHOGENESIS

- In the early stages of spastic hemiplegia, the joints and muscles will be supple, with full passive range of motion.
- With skeletal growth, the muscle imbalance across joints over time leads to muscle–tendon unit shortening and joint contractures, eventually leading to skeletal deformity.
- Increased FCU tone overpowers the decreased strength of the ECRL and ECRB, leading to a wrist flexion posture.

NATURAL HISTORY

- In spastic hemiplegia due to cerebral palsy, the FCU is the most common deforming force, pulling the wrist into flexion and ulnar deviation.
- Over time, the overpull of the FCU leads to contracture of the muscle, which may lead to fixed contracture of the wrist joint.
- Ultimately, a fixed skeletal deformity can occur by the time of skeletal maturity.
- Initial management involves exercises to keep the FCU stretched and to prevent contracture of the muscle.
- If muscle contractures develop, splinting may be necessary to prevent worsening of wrist joint contractures.
- Tendon transfer surgery is best performed before fixed contractures develop.
- If fixed joint contractures and muscle contractures exist, a salvage procedure with muscle lengthenings, wrist fusion, or both may be necessary.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patient evaluation begins with interviewing the parents regarding use of the affected limb.
- Most commonly, children with spastic hemiplegia will show premature hand dominance, favoring the unaffected side even as young as 6 months of age.
- This may be the presenting complaint leading to the diagnosis of cerebral palsy.
- Delay of normal pinch-and-grasp function patterning at 1 year of age is evident.
- Generalized patterns of upper extremity use for activities of daily living, commensurate with the child’s age, are discussed with the parents and child. The clinician also observes for bimanual skills such as doing zippers and buttons, cutting food, and tying shoes.
- The child’s functional use of the hand can be quantified using House’s classification of upper extremity functional use:
  - In this nine-level classification, functional use is assessed as follows: does not use, passive assist (poor, fair, good), active assist (poor, fair, good), and spontaneous use (partial, complete).
  - This provides a baseline that the physician can use to help communicate the functional goals of treatment with the parents.
  - Agreement with the parents on the child’s present overall level of limb function serves as a baseline for comparing the outcome of treatment.
Examinations and tests to perform include:
- Passive range of motion of each joint. If a joint is passively stiff, a joint contracture exists. Tendon transfer surgery is best performed in patients with full passive mobility of all joints.
- Volkman angle test. This test indicates muscle contracture, as the finger flexors are biarticular, crossing both the wrist joint and the finger joints.
- Active range of motion of the wrist. This indicates whether this patient has control to be able to actively extend the wrist. If this is absent, a tendon transfer surgery may be indicated to provide better active wrist extension.
- Active range of motion of the fingers with the wrist held in a neutral position. This test indicates whether a wrist extensor tendon transfer surgery would be helpful. If the patient has better digital control with the wrist in an extended position, then a wrist extensor tendon transfer surgery would be helpful. If the patient has no digital extension, then an FCU tendon transfer should be considered to the EDC. If the patient develops a clenched fist with wrist neutral position, then a wrist extensor tendon transfer would be contraindicated.
- If a patient has full passive mobility of the joints and no muscle contractures of the finger flexors but positions the wrist in significant flexion, leading to impairment with grasp and release or fine motor tasks, then a wrist extensor tendon transfer surgery to improve wrist position would be indicated.
- Stereognosis testing. Impaired stereognosis does not preclude surgical intervention, but it is important to identify it preoperatively as a part of the disability present.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Motion laboratory analysis has been used to assist in determining the position of the joints of the upper extremity during tasks.
- A fine-needle electrode can be used to determine whether phasic control of the muscle occurs during grasp and release.
- A muscle that is well controlled with phasic activity, without significant or continuous spasticity, is the best candidate for muscle–tendon transfer surgery.\(^5\)

**DIFFERENTIAL DIAGNOSIS**
- Wrist flexion posturing due to ineffective wrist extensors, flexor contracture or spasticity, or wrist or carpal abnormalities.

**NONOPERATIVE MANAGEMENT**
- Occupational therapy includes the use of splints, stretching and strengthening programs, and active functional use activities.
- Two types of splints can be used: nighttime serial static splinting for treatment of muscle or joint contractures, and daytime splints for pre-positioning the hand to improve active function.
- The indication for nighttime splinting is contractures.
- If no contractures of the muscles or joints exist, nighttime splinting is not necessary and is a waste of time and money for the child and family!

- If contractures exist at the wrist or fingers and thumb, a nighttime forearm-based wrist–hand orthosis is indicated.
- Daytime splints are usually used to pre-position the wrist in a neutral to slight “cock-up” position to help improve grasp and to pre-position the thumb out of the palm to help improve pinch.
- If the splint is bulky or cumbersome, it will interfere with rather than enhance function, defeating its purpose.
- Care should be given to ensure proper fit of the splint so that its purpose can be achieved.
- Stretching and strengthening programs, along with active functional use activities, are carried out by the therapist as well as taught to the parents and child as a home program.
- For patients with more focal muscle tone imbalance, botulinum toxin type A injections have been shown to be effective in reducing spasticity in the muscles injected and in improving hand function.\(^1,8,9\)
- Botulinum toxin locally blocks the release of acetylcholine at the neuromuscular junction, with a reversible action lasting on average 3 to 4 months. During this period, antagonist muscles can be strengthened and spastic muscles can be stretched, with the benefits lasting beyond the direct effects of the medication.
- For the mildly involved child, treatment with Botox injections may obviate the need for surgical intervention.

**SURGICAL MANAGEMENT**
- The most common deformity of the wrist is flexion, often with ulnar deviation as well. This is the most functionally disabling deformity in hemiplegia as it significantly interferes with grasp and release function.
- Several surgical options exist, with the choice depending on the degree of deformity and the extent of volitional control of each muscle involved.
- The three main options for treatment of a wrist flexion deformity are:
  - Release or lengthening of the deforming spastic muscles (FCU, FCR)
  - Transfer of tendons to augment the weak wrist extension
  - Wrist fusion to stabilize the joint for the severe, fixed, nonfunctioning wrist
- If the wrist flexor deformity is significant and the patient does not have active control of wrist extension, then tendon transfer surgery to augment wrist extension may be necessary.
  - Using the FCU as a transfer to wrist extension has the advantage of removing its force as a spastic wrist flexor and ulnar deviator, and transferring its forces into wrist extension.
  - Care must be taken to prevent overcorrection if the deformity is not severe, or if the transfer is tensioned too tightly, particularly in the younger child.

**Preoperative Planning**
- In all cases of transfer into the wrist extensors, the finger function must be assessed preoperatively with the wrist in neutral, the desired postoperative position.
- If the finger flexors are too tight when the wrist is brought into neutral, a finger flexor lengthening will be necessary as part of the procedure.
If the patient does not have finger extensor control to allow for release of grasped objects, then a transfer into the finger extensors (EDC) may be indicated.

**Positioning**

- The patient is positioned supine on the operating room table, with an armboard to support the upper limb during the procedure (FIG 1).
- A tourniquet is applied above the elbow.

**Approach**

- A volar–ulnar approach to the forearm is used to harvest the FCU tendon, and a dorsal approach to the distal forearm and wrist is used for inserting the tendon transfer.

**Mobilization of the Flexor Carpi Ulnaris**

- The incision for exposure of the FCU is a longitudinal one on the volar and ulnar aspect of the forearm from the proximal third of the forearm to its distal insertion on the pisiform (TECH FIG 1A).
- Dissection is carried out through the subcutaneous layer and the forearm fascia, onto the muscle belly proximally and onto the tendon insertion distally.
  - The ulnar nerve and artery lie radial to the tendon and are carefully identified and protected, including the dorsal ulnar sensory branch in the distal aspect of the wound.
- The tendon is transected at its distal insertion on the pisiform, and a grasping suture is placed (TECH FIG 1B).
- The FCU is then freed of its fascial insertion back to the most proximal aspect of the wound to allow full mobilization of the muscle to its dorsal position (TECH FIG 1C).
- Full mobilization of the muscle to the proximal third of the forearm has been shown to increase its vector as a forearm supinator, in addition to its wrist extension moment arm.²

**Transfer of the Flexor Carpi Ulnaris to the Extensor Carpi Radialis Brevis Tendon**

- A second incision is made over the dorsal radial aspect of the wrist diagonally over the second dorsal compartment (ECRB, ECRL) of the wrist (TECH FIG 2).
- Just distal to where the first dorsal compartment tendons (abductor pollicis longus and extensor pollicis brevis) cross the second dorsal compartment, a generous
fascial window over the second dorsal compartment is made to fully expose the ECRB and ECRL tendons.

- A subcutaneous tunnel is then made in direct line from the proximal end of the ulnar incision to the radial incision to allow a straight line of pull for the tendon transfer.

- The FCU tendon is then woven into the ECRB tendon using the Pulvertaft weave technique and tensioned so that the wrist sits at rest against gravity in a neutral position.

- Standard wound closure is performed after the tourniquet is deflated.

**POSTOPERATIVE CARE**

- The postoperative rehabilitation regimen is imperative to maximize surgical results.
- The limb is immobilized in a cast for 1 month after tendon transfer surgery.
- After 1 month, the cast is removed and a custom splint is used holding the wrist in a neutral position (as well as protecting any other procedures that were done concomitantly).
- The splint is worn full time for an additional month but is removed three to five times a day for active range of motion and light functional activities.
- After 1 month of full-time splinting, the patient then progresses to nighttime splinting only with active functional use of the hand during the day, including lifting and strengthening exercises.
- Individualized sessions with a therapist experienced in tendon transfer rehabilitation are very helpful to maximize use of the limb and incorporate the wrist into activities of daily living, but success may be limited by the overall extent of the patient’s cerebral palsy involvement.

**OUTCOMES**

- The greatest functional benefit in upper extremity surgery has been reported with correction of the wrist flexion deformity, regardless of the transfer used.
- Beach et al. as an example of the correction achieved, reported a postoperative arc of motion of almost 50 degrees, centered around the neutral axis, at greater than 5 years of follow-up.
- Significant aesthetic improvement was noted as well in 90% of patients.
- A functional outcome study of 134 cerebral palsy patients treated surgically showed that the average functional improvement was from use of the hand as a poor passive assist to use of the hand as a poor active assist. This article advocates performing multiple procedures simultaneously for correction of the elbow, forearm, wrist, and thumb in a single surgical setting.

**COMPLICATIONS**

- All surgical procedures carry risk, and this must be weighed against the potential benefits that most commonly are achieved.
- Preoperatively, patients must be screened for anesthetic complications as follows:
  - A bleeding screen for patients on long-term Depakote antiseizure medications
  - Screening for bladder and lung infections, particularly for patients with poor urinary or pulmonary control
  - Nutritional status (height and weight percentiles for age)
  - Intraoperative attention to wound care is imperative to avoid wound healing problems.
  - Wounds may need a postoperative drain to prevent hematoma formation.
Nerve and artery injury can be avoided with appropriate planes of dissection and a thorough knowledge of the pertinent anatomy.

Postoperatively, the splint or cast should be adequate to allow for postoperative swelling and should be split if excessive swelling is encountered.

- Many children with spasticity do not have normal preoperative sensory or motor findings and may not have normal mentation, so normal parameters cannot be used to monitor for compartment syndrome.
- Premature removal of the cast or splint, as well as overzealous patient activities, can lead to tendon rupture or attenuation.
- Excessive immobilization can lead to excessive adhesion formation, diminishing the eventual functional use.
- Long-term problems most commonly involve loss of the muscle balance achieved at the time of the surgery.
  - Many children have tendon transfers as young as 7 years old, with continued skeletal growth, they may have recurrent deformity.
  - Overcorrection can also occur, with the “opposite” deformity occurring. “Fine-tuning” surgery may be necessary to address complications that develop after correction of the original deformity.
  - Several principles will help prevent these complications.
    - Do not overcorrect deformity, particularly in the younger child.
    - Leave options to reverse the surgical correction if necessary.

Keep functional grasp and release as the highest priority in surgical planning.

Avoid wrist arthrodesis, as this precludes the tenodesis effect of the wrist for finger use.

REFERENCES

DEFINITION
- Radial dysplasia represents a spectrum of longitudinal deficiency in radial growth.
- This deficiency can be mild or severe based on the deficiency in the radius.

ANATOMY
- Bayne and Klug\(^1\) have provided a classification based on radiographic findings (Table 1).

PATHOGENESIS
- Radial dysplasia develops during the period of embryogenesis. During this period, other organ systems are developing and may also be affected, as discussed later in this chapter.

NATURAL HISTORY
- The natural history of patients with radial dysplasia clearly depends on the type of dysplasia present and the associated conditions.
- Patients with isolated type I or II radial dysplasia usually do not require surgical intervention.
- Patients with more severe dysplasia can frequently benefit from surgical intervention.
- Many times radial dysplasia is part of a syndrome, and the associated sequelae clearly affect these patients more than the underlying radial dysplasia. The most common associations are with Holt-Oram syndrome, thrombocytopenia-absent radius (TAR) syndrome, Fanconi anemia, and VACTERL (vertebral anomalies, anal atresia, cardiovascular anomalies, tracheoesophageal fistula, esophageal atresia, renal or radial

anomalies, limb anomalies) (in front of or above the central axis of the limb).

- An association with several craniofacial syndromes is also common.
- No matter what procedure is used for treating the radial dysplasia, the patients all have a high incidence of recurrent deformity as they get older.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Clearly the most significant finding is radial deviation at the wrist (FIG 1).
- If the patient is older, the affected forearm will also be short.
- Frequently there is also associated thumb hypoplasia.
- Because of its frequent association with systemic conditions, all patients require careful examination of their cardiac, renal, hematologic, and spinal systems.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs should be taken of both forearms to assess stage of radial dysplasia (see Table 1).
- In addition, all patients warrant a workup for syndromes and associated conditions, such as Holt-Oram syndrome, Fanconi anemia, TAR syndrome, and VACTERL.
  - This requires cardiac, renal, hematologic, and spinal evaluation.

**NONOPERATIVE MANAGEMENT**

- All patients warrant preoperative stretching and splinting before any surgical intervention.
  - This may require external fixation techniques to distract the soft tissues in severe cases.

**SURGICAL MANAGEMENT**

- Patients with type I or II radial dysplasia usually do not require surgical intervention.
- Surgical treatment has generally ranged from soft tissue rebalancing alone to full centralization of the wrist with or without external fixation.
  - Before any procedure is contemplated, the surgeon must remember that the patient must maintain the ability to get his or her fingers to the mouth with the wrist in the surgically altered position.

- We have had experience with various procedures for the treatment of radial dysplasia, including centralization, free toe transfer for stabilization of the radial wrist, and soft tissue release alone. We do not use formal centralization procedures anymore, as we have found the recurrence rate to be similar to our soft tissue release procedure. In addition, we think that this procedure jeopardizes the ulnar epiphysis, which can lead to an extraordinarily short forearm. Also, loss of mobility can result from a successful centralization procedure.
- Vascularized bone transfer can be used in selective cases to provide stabilization of the radial side of the wrist. In the past we have used a vascularized second-toe metatarsophalangeal joint as described by Vilkki. In the future we anticipate using the proximal fibula, as its growth potential may be more similar to the ulna than the metatarsophalangeal joint.
  - The long-term problem for any surgical procedure is the recurrence rate.
- For our patients, soft tissue release with a bilobed flap reconstruction has provided the most reliable, effective results.

**Preoperative Planning**

- Before surgery, the patient must have undergone adequate soft tissue stretching.
  - In the first few months this is accomplished by splinting. In severe cases, serial casting may be necessary.
  - The splints should be large enough so the child cannot swallow it.
  - After about 6 months of age, active stretching is started by the parents with use of nighttime splinting.
- The bilobed flap design must be drawn appropriately to take advantage of the redundant tissue on the ulnar side of the wrist.

**Positioning**

- The patient is placed in the standard supine position, and a general anesthetic is used in all cases.
- We do not use a standard tourniquet as we have found this to be inadequate in young children. Instead, we use the elastic bandage as a tourniquet in the upper arm.

**Approach**

- We use a dorsal surgical approach, although more recently a volar approach has been described that may provide better exposure for soft tissue release.
Part 4 PEDIATRICS • Section VI UPPER EXTREMITY

RELEASE OF RADIAL DEVIATION OF THE WRIST

- After induction of general anesthesia, the upper extremity is prepared and draped in the usual fashion.
- The bilobed flap is then carefully designed using a marking pen (TECH FIG 1A,B).
- The Esmarch bandage is used to exsanguinate the limb; it is then wrapped three times around the upper arm for use as a tourniquet.
- After careful incision and elevation of the skin flaps (TECH FIG 1C), the finger and extensor tendons as well as the median nerve are carefully identified and preserved.
- All other tissues in the radial wrist are released. Care must be taken not to dissect excessively near the ulnar epiphysis, to prevent injury to the vascular supply to this area.
- After release is accomplished, the wrist is placed in a neutral position and pinned with a 0.062-inch Kirschner wire. The Kirschner wire is temporary and is put across the joint from either direction (ie, there is no specific location for the exit or entrance site).
- The flaps are then rotated and sutured in place (TECH FIG 1D,E).
- The tourniquet is removed to ensure perfusion to the fingers, and a long-arm cast is placed.

PEARLS AND PITFALLS

| Adequate preoperative stretching of soft tissues | If not adequate, this may lead to a suboptimal result. |
| Identification of median nerves and tendons, as these structures tend to be in very aberrant locations | There is the potential for injury to nerve or tendon during soft tissue release if this is not done. |
| Careful dissection around the distal ulna | If too aggressive, it can lead to injury to the epiphyseal region, leading to growth problems in the ulna. |
| Pinning of ulnocarpal joint after release | Failure to do this can lead to partial flap loss because of motion at the joint. |
POSTOPERATIVE CARE
- The long-arm cast is left on for 3 to 4 weeks.
- At that point the pin is removed and the patient is changed to a removable splint.

OUTCOMES
- The bilobed flap procedure is an effective procedure for treating radial dysplasia (FIG 2).
- Deformity tends to recur, though the incidence of this appears to be similar to that for other procedures used to treat radial dysplasia.

COMPLICATIONS
- Very few complications are associated with this procedure.
- Partial flap loss can occur, but the risk seems to be minimized by appropriate flap design and immobilization after the procedure.

REFERENCES
DEFINITION
- Multiple hereditary exostoses (MHE), first described by Boyer in 1814,\(^2\) is a familial disorder with an autosomal dominant mode of inheritance.\(^8\) It is also known as multiple osteochondromatosis, multiple osteochondromata, multiple cartilage exostoses, diaphyseal aclasis, or metaphyseal aclasis.\(^5,18\)
- MHE is a developmental disorder affecting numerous sites in the immature skeleton, except the skull. It is characterized by abnormal proliferation of epiphyseal chondroblasts that causes a subsequent defect in remodeling of the metaphysis. In the immature individual this leads to the two main characteristics of this condition: skeletal metaphyseal bony prominences capped with cartilage (exostoses) and retardation of longitudinal bone growth.

ANATOMY
- Knowledge of the normal anatomy and biomechanics of the forearm in the immature individual is instrumental in understanding the pathogenesis of the deformity, and ultimately in planning appropriate treatment.
  - The ulna acts like a swivel hinge around which the radius rotates.
  - During forearm pronation–supination the relationship between the two forearm bones changes. This rotational movement requires perfect alignment of both radius and ulna as well as integrity of the ligamentous structures around the proximal and distal radioulnar joint and the interosseous membrane. Minimal axial or rotational bone deformity, asymmetric bone shortening, or ligament instability can hinder this function.

PATHOGENESIS
- Osteochondromas are the most common benign bone tumor. Histologically, they resemble the epiphyseal growth plate and consist of a bony stalk covered by a cartilaginous cap. They arise from the peripheral aspect of the growth plate of bones that undergo enchondral ossification.\(^10\)
  - About 15\% of osteochondromas occur as MHE.\(^22\) In MHE, the exostoses vary greatly in number, location, size, and configuration. They tend to have a more irregular and bizarre shape than solitary osteochondromas. They also typically involve a significantly greater portion of the metaphysis or diaphysis. Progressively larger and more mature-appearing lesions with ossification are seen on the surface of the bone as the distance from the physis increases, so they appear to be migrating into the diaphysis of long bones.\(^10\)

NATURAL HISTORY
- The prevalence of MHE in the general population is estimated to be at least one in 50,000, with a median age of first diagnosis of 2 to 3 years of life (exostoses rarely develop before 2 years of age).\(^17\)
  - In individuals with MHE an average of five or six exostoses, involving both upper and lower extremities, are found at the time of the first consultation.\(^22\)
  - Over time the upper and lower extremities may appear disproportionately shorter compared to the trunk.
  - The phenotypic penetrance of this condition is age-related. By 2 to 3 years of age, 50\% of the affected individuals show signs of the disease; the presence of exostoses is almost always evident by the age of 12. Once skeletal maturity is achieved most of the lesions will become quiescent and often will ossify.\(^17\) The overall penetrance of the disease in adult obligate heterozygotes ranges between 93\% and 100\%,\(^7,8,28\)
  - Approximately 10\% of individuals with documented manifestations of multiple exostoses have no family history of MHE.\(^17\)
  - It is reported that 30\% to 60\% of the individuals with MHE show a deformity of the forearm.\(^17\) The natural history of forearm deformities is progressive and results in a variable and worsening amount of weakness, pain,\(^4\) functional problems (such as dislocation of the radial head, limited pronation–supination, ulnar deviation at the wrist, and compression on adjacent structures), and cosmetic deformity.
  - The deformities are almost always accompanied by discrepancy in length between the two bones. The asynchronous rate of longitudinal growth in an anatomic region where two bones are paired in close longitudinal relationship leads to a greater risk of anatomic distortion. Most of the longitudinal growth of the ulna occurs at the distal physis,\(^16\) which is also the more commonly affected physis (30\% to 85\% of the cases).\(^17,18\)
  - A serious complication of MHE is the potential for malignant transformation of an exostosis into chondrosarcoma. This can occur at any age but it is exceedingly rare during childhood.\(^17\)
  - The risk of malignant degeneration in adults with MHE is 0.57\% to 5\%.\(^8,17,28\)
  - The clinical course of the chondrosarcoma is slow and the prognosis is in general favorable if the tumor is detected early. Metastases occur late, usually to the lung, via hematologic dissemination.
  - Patients affected by MHE have a normal life expectancy unless malignant degeneration and metastasis develop.\(^22\)

HISTORY AND PHYSICAL FINDINGS
- In the context of progressively enlarging, juxta-articular protuberances, the characteristic forearm deformities may develop.
  - An accurate physical examination of the upper extremity, including evaluation of the comparative length of the forearms as well as range of motion of the elbow, wrist, and forearm (flexion and extension, radial and ulnar deviation of the wrist, varus and valgus angle of the elbow, and pronation–supination of the forearm), is instrumental to assess the progression of the condition.
  - The classic clinical description is a bowed, short, and knobby-appearing forearm with the wrist in an ulnarly deviated position, which limits radial deviation.
During growth the affected ulna typically remains relatively shortened and curved, and this often leads to significant bowing of the radius. When the ulna is shorter the ulnar collateral ligament acts as a tether, causing bowing of the radius. In addition, the local presence of the exostosis itself causes radial bowing by disturbing hemiepiphyseal growth.12 Cubitus varus deformity, radial head dislocation, or both may also occur. Radial head dislocation is reported to occur in 22% of the affected forearms.18 Symptoms of this can be varus deformity of the elbow, limitation of elbow motion, and pain. A mild flexion deformity of the elbow is often present. At the wrist level an increased ulnar tilt of the radial epiphysis, ulnar deviation of the hand, and progressive ulnar translocation of the carpus are often present. These deformities lead to a loss of radial deviation of the hand and loss of pronation–supination of the forearm (FIG 1).

The earliest radiologic sign is an asymmetric or beaked overgrowth of the cortex next to the growth plate.3 Like solitary osteochondromas, the exostoses may be described as sessile, pedunculated, or cauliflower-like; they nearly always point away from the physis. In MHE, the lesions tend to be bigger and have a more bizarre shape. Characteristically

IMAGING AND OTHER DIAGNOSTIC STUDIES

The diagnosis of MHE can be easily made by clinical inspection in a child with a positive family history. Plain radiographic evaluation is usually sufficient to confirm the diagnosis and to determine the number, location, and morphology of the exostoses (FIG 2).
Part 4 PEDIATRICS • Section VI UPPER EXTREMITY

Differential Diagnosis

- Langer–Giedion syndrome
- Madelung deformity
- Chondrosarcoma

in the distal ulna they are often narrow, with a pointed end (FIG 2).

In older children and teenagers, irregular areas of calcification of the cartilaginous cap may be present, particularly in the more voluminous lesions. Extensive calcification with changes in the shape and thickness of the cartilaginous cap should raise suspicion of a possible chondrosarcomatous transformation.

At least two full views of the forearm (true anteroposterior and lateral containing both the elbow and the wrist) are necessary to properly assess the ulna variance, the radial articular angle (RAA), the carpal slip, and the relative radial bow. These radiographic measurements are useful in the surgical planning phase (FIG 3).1

Alterations of the radial head on radiographs must always be assessed. They range from hypertrophy and flattening to a complete radial head dislocation.

The Taniguchii classification correlates the regional involvement of the forearm with the generalized severity of the disease.23

Masada morphologically classified the involvement of the forearm in MHE into three types (FIG 4).12 This classification was also used for treatment planning.

Computed tomography (CT), magnetic resonance imaging (MRI), and magnetic resonance angiography are performed at times for specific and symptomatic lesions. These can be especially helpful to detail the anatomic position relative to soft tissue structures, or when malignant transformation is suspected.24

Differential Diagnosis

- Langer–Giedion syndrome
- Madelung deformity
- Chondrosarcoma

Nonoperative Management

- The only treatment for MHE is surgery, but the mere presence of an exostosis is not, by itself, an indication for surgical removal.
- The conspicuous number of lesions and the fact that they are mostly asymptomatic warrant a cautious surgical approach.

Surgical Management

- Surgical treatment of forearm deformities in MHE remains controversial. A number of operative techniques have been proposed.5,16,12,19
- The main surgical indications are:
  - To improve forearm function (pronation–supination)1
  - To relieve pain from external trauma or irritation of the surrounding soft tissue4
  - To improve appearance
  - To rule out malignancy when there is a rapid increase in size of a lesion15
- When evaluating the surgical indications in an individual patient, it is important to distinguish between the functional deficit and the cosmetic appearance.
  - The postoperative appearance of the forearm has been shown to be unrelated to the functional outcome.14
  - Despite maintaining good function even without treatment,1,14 a percentage of patients find the arm cosmetically unpleasant because of the shortening, angulations, and deformities.14 If surgery is being undertaken for cosmetic rather than functional purposes, the hopes, concerns, and expectations of patient and parents must be thoroughly discussed and accurately outlined.
- If function is the main concern, the goal of surgery is to maintain or improve function until reaching skeletal maturity and not to prevent the deformities.
- Some authors5,12,15 advocate an aggressive approach based on the rationale that forearm deformities are equal to functional impairment. Their surgical treatment employs procedures such as excision of the exostoses and ulnar lengthening, associated at
times with radial hemiepiphyseal stapling or osteotomy. They feel this is the only way to prevent the development or progression of deformity in the upper extremity.

- According to these authors, the surgical indications include relative ulna shortening (with or without bowing) of more than 1.5 cm, RAA of greater than 30 degrees, carpal slip of more than 60 degrees, and bowing of the radius or the ulna (or both).\(^5\)
- However, we and others believe that the mere presence of forearm deformities alone is relatively unrelated to functional impairment,\(^1,14,21\) and therefore we do not recommend surgical correction of the deformities only to prevent a possible, but not predictable, future functional impairment.
- Symptomatic dislocation of the head of the radius is defined as interfering with joint motion or causing significant pain.

**Procedures**

- Exostosis excision alone is indicated when a lesion becomes symptomatic or when it alone causes limitation of forearm pronation–supination. This procedure alone does not correct the forearm deformities that may be present.

  - If significant forearm deformity is present, exostosis excision is combined with ulnar tether release with or without radial osteotomy.
  - Radial osteotomy is performed in the skeletally mature or nearly skeletally mature patient, as significant remodeling of the radius is unlikely.
  - If the patient has significant growth potential remaining, ulna-tether release alone can lead to impressive correction.
  - Ulna lengthening with or without radius epiphyseal stapling remains a common procedure reported in the literature, but we do not use this regularly. We think it can lead to a shorter forearm, as well as bearing the incumbent risks associated with lengthening procedures.
  - The treatment for symptomatic radial head dislocation is usually surgical excision once the patient is skeletally mature. Excision before this time may lead to instability, growth disturbances, and possible worsening of the wrist or elbow deformity. In rare instances, however, exostosis excision with ulnar osteotomy may be effective in relocating the radial head.

---

### EXOSTOSIS EXCISION AND ULNAR TETHERING RELEASE

- The location of the incision in the distal forearm varies depending on where the osteochondroma is located. Planning of this is important, as the ability to access the distal ulna is imperative whether the osteochondroma is located on the distal ulna or radius.
  - If the patient has ulnar involvement only, the incision can be placed on the subcutaneous border of the ulna between the flexor carpi ulnaris and the extensor carpi ulnaris. Care must be taken to identify and preserve the dorsal branch of the ulnar nerve.
  - If the patient has osteochondroma of both the radius and ulna, the incision has to be modified to allow exposure of both bones as well as the distal ulna.
  - A tourniquet of appropriate size is used.

  - Once the initial incision is made, the osteochondroma is carefully exposed and excised (TECH FIG 1A–C). Care must be taken to preserve satisfactory bony cortex for stability.
  - Next, the distal ulna is exposed and the ulna-tethering force is released.
  - This is usually done by transecting the distal ulna through the epiphyseal area, leaving the triangular fibrocartilage complex attached to the distal fragment.
  - In the skeletally mature patient a radial osteotomy can be performed if the forearm bowing and deformity is severe (TECH FIG 1D–F).
  - Wire fixation is usually adequate for the osteotomy.
  - As stated earlier, in the skeletally immature patient, release of the tether alone is usually adequate.

---

**TECH FIG 1**

- **A.** Exposure of large osteochondroma of the distal ulna.
- **B.** Dissection and exposure of the osteochondroma. Significant tethering is present distally. (*continued*)
TECH FIG 1 • (continued) C. After excision of osteochondroma and release of ulnar tethering. D. In a skeletally mature patient, a radial osteotomy is performed after exostoses excision and ulnar-tether release. E. After excision of exostoses, ulnar-tether release, and radial osteotomy. F. Radiograph taken 30 months after surgery shows improved forearm–wrist alignment.

RADIAL HEAD EXCISION

- An incision is made over the prominent radial head with the forearm in pronation to protect the posterior interosseous nerve.
- Dissection is then carried down in the interval between the anconeus muscle and extensor carpi ulnaris.
- The radial head is then exposed and excised (TECH FIG 2).
- Layered closure is then performed and the extremity is immobilized for 2 weeks, followed by institution of range-of-motion exercises.

TECH FIG 2 • A. Patient with painful radial head dislocation. B. Exposure of the radial head. Forearm is in a pronated position. C. Radial head exposed before excision. D. Excised radial head. Significant degenerative changes are present.
To improve the bone formation and reduce the risk of fracture at the lengthening site, when the ulna is lengthened, the cordlike portion of the interosseous membrane tends to pull the radius distally. This action is advantageous when concomitant radial head dislocation is present. Otherwise, the cordlike portion of the interosseous membrane should be dissected to prevent migration of the radius.11

The ulnar lengthening is fraught with complications, reported.1,5,12,13,15,16 This calls into question the indications for this procedure. The main complications in progressive distraction lengthening are nerve damage, fractures at the lengthening site, and pin tract infection. When only the ulna is lengthened, the distraction lengthening of the forearm bones, the bone formation takes longer compared to the lower limb because of the lack of weight bearing. Therefore, one of the disadvantages of this technique is that the external fixator must be kept on for several months.

To improve the bone formation and reduce the risk of fracture at the lengthening site, dynamization techniques are recommended.

When the ulna is lengthened, the cordlike portion of the interosseous membrane tends to pull the radius distally. This action is advantageous when concomitant radial head dislocation is present. Otherwise, the cordlike portion of the interosseous membrane should be dissected to prevent migration of the radius.11

OUTCOMES

Many MHE patients do not need surgery. In patients who require surgery, we feel that ulnar-tether release, with or without exostoses excision, with or without radial osteotomy, provides the most reliable result with the fewest complications. In selected patients this can greatly improve function, in addition to the improved cosmesis of the extremity.

For symptomatic radial head dislocations we prefer excision, as this usually leads to a consistent, reproducible result with little risk.

COMPLICATIONS

The ulnar lengthening is fraught with complications, reported in the literature to range from 0% to 100%.1 Recurrence of the deformity in the skeletal immature patient is commonly reported.1,5,12,13,15,16 This calls into question the indications for this procedure.

The main complications in progressive distraction lengthening are nerve damage, fractures at the lengthening site, and pin tract infection. When only the ulna is lengthened, the distracting tension is not exerted directly on the neurovascular bundle, with minimal risk of nerve dysfunction.

When performing radial head excision, the surgeon has to be careful in the initial dissection to avoid injury to the posterior interosseous nerve as well as to the stabilizing structures of the elbow.

REFERENCES

DEFINITION
- Sprengel deformity is characterized by congenital high elevation of the scapula and medial rotation of the inferior pole of the scapula. The exact cause of the deformity is unknown.
- Associated anomalies include Klippel-Feil syndrome, rib deformities, omovertebral bone formation, muscle anomalies, clavicle hypoplasia, tracheoesophageal fistula, anal stenosis, kidney anomalies, diastematomyelia, and scoliosis.
- Eulenberg first described three cases of congenital “high dislocation of the scapula” in 1863, and in 1880 Willet and Walsham were the first to describe the omovertebral bone—a broad osseous band of bone connecting the scapula with the spinous process of C6.

ANATOMY
- The normal scapula forms in the 5th week of fetal development adjacent to the level of C5 and then descends to the dorsal thoracic area at a level between T2 and T8.
- The scapula in Sprengel deformity is abnormally high, has a decreased vertical diameter, and is deformed in shape.
- The supraspinous region is rotated anteriorly in a convexity near the shape of the dorsal thorax.
- The inferior aspect of the scapula is rotated medially.
- The scapula in Sprengel deformity may be attached to the lower cervical vertebrae (usually C6) by an abnormal band of tissue, which may be fibrous, cartilage, or bone (ie, omovertebral bone).
- The musculature of the shoulder girdle may be hypoplastic, absent, or weak.
- The trapezius muscle, the levator scapulae muscle, and the rhomboid muscles often are hypoplastic.
- The trapezius is the most commonly affected muscle. Other muscle groups that attach to the scapula occasionally are affected.
- Associated bony congenital anomalies include Klippel-Feil syndrome, fused ribs, cervical ribs, congenital scoliosis, cervical spina bifida, hypoplastic clavicle, and short humerus.

PATHOGENESIS
- The normal scapula develops in the cervical region and then descends to the upper posterior area of the thorax by the end of the 3rd month of fetal development.
- Sprengel deformity occurs as a result of interruption of the normal caudal migration of the scapula during fetal development.
- The cause of Sprengel deformity is unknown, but the following theories have been proposed:
  - Cerebrospinal fluid escapes through a “bleb” in the membrane of the roof of the fourth ventricle into the adjacent tissue of the neck to cause malformations.
  - Heredity (there have been several reports of familial occurrence)
  - Increased intrauterine pressure

NATURAL HISTORY
- The Sprengel deformity is present at birth, and the location of the scapula in relation to the neck and thorax remains constant as the child grows.
- The abnormal scapula appears to grow proportionally to the growth of the child.
- Associated congenital anomalies such as congenital scoliosis may progress, thereby changing the appearance of the deformity.

PATIENT HISTORY AND PHYSICAL FINDINGS
- At birth, the shoulder with a Sprengel deformity appears to be displaced upward and forward.
  - In unilateral cases, shoulder asymmetry is evident.
  - The left scapula is involved more commonly than the right (FIG 1A).
  - In bilateral cases, both shoulders appear to be high, and the neck may appear thick and short.
- The scapula may be tilted upward.

FIG 1 • A. Sprengel deformity of the right shoulder.
B. Appearance of Sprengel deformity when the right arm is held in maximum abduction.
Motion of the shoulder is reduced in abduction and elevation (FIG 1B).
- Muscle weakness or hypoplasia can be observed in the shoulder area.
- Torticollis may be present.
- Scoliosis and kyphosis as well as deformities of the chest from rib anomalies may be observed.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Radiographs of the shoulder and neck show the bone deformities (FIG 2).
- Sonography of the spinal cord is helpful in infants younger than about 4 months of age who have congenital spine anomalies.
- Sonography can be performed through the cartilage of the lamina and spinous process, but after about 4 to 5 months of age, ossification blocks the views.
- Congenital spine anomalies have a high association with intraspinal abnormalities.
- Sonography of the kidneys is helpful in cases associated with congenital spine anomalies.
- MRI is extremely helpful for evaluating muscle and soft tissue development.
- CT (with 3D reconstruction) is helpful to define the extent of bone deformity. CT provides excellent visualization of the omovertebral structure.
- Both still and video photography are helpful to record pre- and postoperative appearance and to document function.

**NONOPERATIVE MANAGEMENT**
- In infants and young children, passive and active stretching exercises may be performed daily to maintain motion of the shoulder.

**SURGICAL MANAGEMENT**
- Operative procedures are designed to improve the appearance of the elevated shoulder and, to a limited extent, to improve its function.2,7,8,10,11,13,15
- Operative treatment can be considered in cases in which the deformity is disfiguring and shoulder function is impaired.
- In children with mild deformities in which the appearance of the shoulder is acceptable, operative treatment probably is not indicated.
- The recommended age for surgery is 3 to 8 years.

**Preoperative Planning**
- Preoperative evaluation of the appearance of the deformity with photographs is advised.
- The author prefers full-profile photographs taken from the frontal, posterior, and both side views.
- Motion can be documented by a series of photographs taken with the arms extended, elevated, and abducted.
- Videos of the patient performing motion activities of the shoulder are helpful to determine the degree of deformity and whether or not the appearance is acceptable.
- The Cavendish grading scale is helpful in evaluating appearance:
  - Grade I (very mild): shoulder joints are level, and the deformity is not obvious when the patient is dressed.
  - Grade II (mild): shoulder joints are level, but the deformity is visible when the patient is dressed.
  - Grade III (moderate): the involved shoulder is elevated 2 to 5 cm, and the deformity is obvious.
  - Grade IV (severe): the involved shoulder is greatly elevated, and the superior angle of the scapula is near the occiput.
- Preoperative evaluation of shoulder motion
- Occupational therapy measurement of combined abduction of both shoulders (combined glenohumeral and scapulothoracic movement) as well as other shoulder motion is useful.
- Shoulder functional testing also may be useful.
- The author uses radiographs at the extremes of motion to verify the degree of measurements.
- The anomalies of the shoulder, spine, and rib cage must be evaluated radiographically.
- CT scanning and MRI are helpful to determine both bone and soft tissue abnormalities.
- Currently, the author uses somatosensory evoked potentials and transcranial electrical motor evoked potentials to evaluate the brachial plexus nerve function during surgery.
- Baseline values are obtained after the induction of anesthesia, and monitoring is continued during the procedure.

**Positioning**
- The patient is placed in the prone position with the head positioned as if facing forward.
- The entire arm, the shoulder, and the posterior thorax back area (ie, superiorly from the high cervical area, inferiorly to the lumbar area, and laterally to the contralateral scapular area) are prepared and draped.
- The arm and scapular girdle are left free for manipulation during the operation.
- Leads for the somatosensory evoked potentials and transcranial electrical motor evoked potentials are positioned on the skin and muscles in sterile fashion.

**Approach**
- The Woodward procedure consists of detaching the origins of the trapezius and rhomboid muscles from the spinous process and moving them downward after resection of the omovertebral bone and any fibrous bands from the scapula.17
- The procedure described by Green7 involves division of the muscles connecting the scapula to the trunk, excision of the omovertebral bone, excision of the supraspinous portion of the scapula, and reattachment of the muscles to hold the scapula reduced.

**FIG 2** AP radiograph of the right shoulder of a child with Sprengel deformity.
The modification described by Borges et al\(^1\) is performed as originally described by Woodward,\(^2\) with the addition of excision of the medial border of the scapula and resection of the supraspinous portion of the scapula.

- The muscles attached on the medial and superior borders of the scapula are reflected extraperiosteally to facilitate bony resection.

Bone resection superiorly is medial to the suprascapular notch, and about 1 cm of the medial border of the scapula is excised.

The author does not usually recommend routine osteotomy of the clavicle, but it is indicated if neurologic issues arise during surgery. The procedure may be performed at the discretion of the surgeon to diminish the risk of neurologic problems.

### MODIFIED WOODWARD PROCEDURE

#### Incision and Dissection

- A midline incision is made that extends from the spinous process of the C4 distally to the spinous process of T9 (TECH FIG 1A).

- The skin and subcutaneous tissue are undermined on the involved side laterally to the medial border of the scapula and the lateral border of the trapezius.

- The trapezius is bluntly dissected from the underlying latissimus dorsi.
  - To achieve this, bluntly dissect the lateral border of the trapezius muscle in the inferior aspect of the operative area from the latissimus dorsi muscle.
  - Continue the dissection medially to the origin of the trapezius at the spinous process of T9. The fibers of the trapezius blend into the fibers of the other muscles that originate from the spinous processes.

- Detach the trapezius distally and proceed superiorly by detaching the remainder of the trapezius and then the rhomboid muscles to the level of the spinous process of C4 (TECH FIG 1B).

- Retract the trapezius and rhomboid muscles laterally.
  - The levator scapulae muscle is identified as it originates from the superior medial aspect of the scapula and courses toward the spinous process of the cervical vertebra.
  - Occasionally, the muscles are fibrotic, which makes identification and dissection more difficult.

- The omovertebral structure (which may be fibrotic, cartilage, or bone) is under the levator scapulae muscle.
  - The omovertebral structure is excised extraperiosteally by sharp dissection.
  - Any fibrotic bands in the area that may limit inferior mobility of the scapula are incised.

- During the dissection, the spinal accessory nerve and the nerve to the rhomboids must be protected as they course beneath the trapezius muscle.
  - The spinal accessory nerve is in line with the vertebral border of the scapula.
  - In cases involving significant fibrosis of muscles, the nerves may be difficult to identify, and the use of spontaneous or electrical triggered electromyography may be helpful.

- The levator scapulae muscle is divided at the superior medial corner of the scapula.

- The transverse cervical artery, which is deep to the levator scapulae muscle, must be protected at the superomedial area of the scapula, because bleeding occasionally can be problematic.

#### Scapular Resection and Reduction

- Superiorly, the scapula is excised medially to the suprascapular notch, after which approximately 1 cm of the medial border of the scapular is excised (TECH FIG 2).
- The scapula can be lifted, and any fibrotic bands between the undersurface of the scapula and chest wall are incised.
- The scapula can now be drawn inferiorly and reduced to a more normal anatomic level.
- Any fibrotic bands that prevent the reduction may be incised.
- As the scapula is reduced, the somatosensory evoked potentials and the transcranial electrical motor evoked potentials should verify the function of the nerves to the arm.
  - During reduction, the nerves of the brachial plexus may become entrapped between the clavicle and the chest wall.
  - If the evoked potentials become abnormal, the scapula is replaced in the elevated position, and clavicular osteotomy\(^1\) is recommended.

**TECH FIG 1** • A. Location of the incision. B. Dissection of the trapezius and rhomboid muscles from the spinous processes of the vertebrae.
**Clavicular Osteotomy**
- A 2-cm incision is made over the middle clavicle area.
- Beneath the platysma muscle, the periosteum is incised longitudinally, and the clavicle is exposed by subperiosteal elevation.
- The author prefers to use a rongeur to incise the clavicle.
- The incised bone chips are used as graft in the osteotomy.
- The periosteum and operative wound are closed in layers.
- The scapula is reduced, and the rhomboid muscles (and fascia) and the trapezius muscle are reattached in a more caudad position at the midline to the ligaments between the spinous processes.
- The latissimus dorsi muscle can be lifted to allow the inferior wing of the scapula to be positioned beneath it.
- The inferior tip of the scapula wing can be sutured to the latissimus dorsi muscle.
- The operative wound is closed in layers, and wound suction drainage may be used at the surgeon’s discretion.

**PEARLS AND PITFALLS**
- Somatosensory evoked potentials and transcranial electrical motor evoked potentials are helpful to monitor the neurologic status of the arm. ■ May indicate brachial plexus compromise and the need for a clavicular osteotomy
- Resection of the prominent superior and the medial border of the scapula ■ Offers the opportunity to improve both appearance and functional outcomes
- Osteotomy of the clavicle ■ May prevent brachial plexus palsy

**POSTOPERATIVE CARE**
- Postoperatively, the arm is maintained in a Velpeau bandage for about 4 weeks.
- Physical therapy is initiated after removal of the Velpeau bandage, with emphasis on glenohumeral motion and muscle strengthening.

**OUTCOMES**
- In my patient group, at an average of 8 years postoperatively, the glenohumeral/scapulothoracic motion was 150 degrees (range, 100 to 180 degrees). This represents 45 degrees improvement from preoperative measurements.1
- In the author’s case, the appearance of all of the children was improved by at least one Cavendish grade, and most achieved grade I or II.
- One out of 14 cases was grade III, and that child had multiple spinal deformities and scoliosis adjacent to the Sprengel deformity.1

**COMPLICATIONS**
- Brachial plexus palsy
- Nerve palsy
- Persistent scapular winging
- Incomplete correction
- Vascular problems
- Wound infection
- Operative scar appearance

An account of the dissection of the parts removed after death from the body of a woman the subject of congenital malformation of the spinal column, bony thorax, and left scapular arch; with remarks on the probable nature of the defects in development producing the deformities. Med-Chir Trans London 1880;63:256.
**DEFINITION**
- The sternocleidomastoid (SCM) muscle is a major muscle of the neck that laterally flexes and rotates the head.
- The term torticollis comes from the Latin words tortus (twisted) and collum (neck). It refers to a clinical deformity where the head tilts in one direction and the neck rotates to the opposite side involuntarily.
- Congenital muscular torticollis (CMT) associated with a contracture of the SCM muscle is the most common etiology of torticollis in infants.
- CMT is the third most common congenital deformity, next to developmental dysplasia of the hip and congenital clubfoot. The incidence of CMT ranges from 0.4% to 1.3%.
- Shortening and contracture of the SCM muscle results in tightness that gives the typical clinical appearance, which is detected at birth or shortly thereafter.
- Cheng et al. subdivided the CMT patients into three groups:
  - Clinically palpable sternomastoid “tumor” or pseudotumor
  - Muscular torticollis group without palpable or visible tumor but with clinical thickening or tightness of the SCM on the affected side
  - All the clinical features of torticollis with neither a palpable mass nor tightness of the SCM muscle

**ANATOMY**
- On each side, the SCM muscle passes obliquely across the side of the neck and divides the neck into anterior and posterior triangles.
- It originates from two heads:
  - Sternal head: superior and anterior surface of manubrium sterni.
  - Clavicular head: superior surface of medial third of clavicle. With the two heads combining, the muscle ascends laterally and posteriorly to insert in the mastoid process of the temporal bone.
- The functions of sternocleidomastoid are multiple:
  - With unilateral contraction, it:
    - Flexes the head and cervical spine ipsilaterally
    - Laterally rotates the head to the contralateral side
  - With bilateral contraction, it:
    - Protracts the head
    - Extends the incompletely extended cervical spine
- The SCM is innervated by the:
  - Spinal accessory nerve (XI)
  - Ventral ramus of second cervical nerve (C2)
- The spinal accessory nerve penetrates the deep surface of the SCM muscle, giving off a branch that supplies it. It passes to the posterior aspect of the SCM deep to Erb’s point.
- Erb’s point is located roughly in the middle of the posterior border of the SCM muscle. At this point, the anterior branch of the greater auricular nerve crosses the SCM.
- The external jugular vein is located anterior to the SCM muscle at the proximal part. It crosses the SCM muscle obliquely at its midpoint and ends at the subclavian vein posterior to the SCM muscle.
- The SCM protects the carotid artery and internal jugular vein, both of which lie deep to it.
- The clavicular origin of the SCM muscle can vary in size. In some cases, the width of the clavicular attachment may extend to the midpoint of the clavicle.
- The anatomy of the SCM muscle and important surrounding structures is shown in **FIGURE 1**.

**PATHOGENESIS**
- The most common etiology of CMT in infants is contracture or shortening of the SCM muscle.
- Infants with CMT most often have a history of difficult or traumatic delivery.
- Davids et al. reported that the position of the head and neck in utero or during labor or delivery can lead to local trauma to the SCM muscle. This is the only muscle in the SCM muscle compartment demonstrated by cadaver studies.
- Progressive fibrosis and contracture of the SCM muscle may be the sequelae of an intrauterine or perinatal compartment syndrome.
CMT may occur in association with oligohydramnios, multiple births, first-born children, and developmental dysplasia of the hip (DDH).

These data support the theory of intrauterine restricted fetal motion and malpositioning of the head and neck. These conditions may be associated with more difficult and traumatic deliveries.

However, CMT found in the infants who are delivered by cesarean section is not consistent with the theory of birth trauma.

The data that show 20% coexistence of developmental dysplasia of the hip support the theory of intrauterine malposition and crowding.9

About 50% of patients with CMT are born with a clinically palpable SCM tumor.1,5 This tumor or pseudotumor is believed to be a developing hematoma that undergoes subsequent fibrosis. This could result from either birth trauma or intrauterine malposition.

Electron microscopy studies revealed that the existence of myoblasts in the interstitium of the mass at different stages of differentiation and degeneration might have a significant bearing on the pathogenesis of torticollis.13

Tang et al13 explained the success of conservative management (stretching exercises) with the presence of myoblast cells besides fibroblast cells.

In vitro, myoblasts could be mechanically stimulated to undergo both hypertrophy and hyperplasia by intermittent stretching and relaxation.

The pathogenesis of the torticollis resulting from pathologies other than CMT is affiliated with other conditions or syndromes.

NATURAL HISTORY

Diagnosis of CMT is usually made at or near birth. Other causes of torticollis generally present later (4 months to 1 year).

A mass (SCM tumor) or fullness in the SCM muscle usually exists within a few weeks or months after delivery.

Typically, the mass decreases in size and disappears between 6 and 12 months of age.

If it remains untreated, contraction and sometimes a fibrous bundle can occur in the muscle.

Flexion and rotation deformity of the neck begins in infancy.

Typically the head turns toward the involved side and the chin points to the opposite shoulder.

Plagiocephaly and facial asymmetry may be present early on; they increase with time.

However, in persistent cases, deformity progresses and becomes inflexible.

Flattening of the skull and facial bones can develop on the affected or normal side depending on the sleeping position of the child.

If the child remains untreated until 5 to 7 years of age, contraction of the neck with limited motion becomes resistant to correction. The deformity of the cranium and facial bones also becomes less amenable to spontaneous correction.

Formation of a lateral band is mostly responsible for limited neck mobility.

In older children with persistent deformity, radiographic abnormalities can also occur; they include asymmetry of the articular facets of the axis, tilt of the odontoid process to the side of the torticollis, and possibly cervicothoracic scoliosis.2,12

PATIENT HISTORY AND PHYSICAL FINDINGS

A complete history and physical examination should be done in newborns with torticollis.

The incidence of the breech presentation and birth trauma in children with CMT is higher than the general population.

There is known coexistence of DDH with torticollis.

The reported incidence of DDH with CMT varies from 8% to 20%.9,15

A clinical examination of the hip and ultrasonography screening are thus required for children with CMT.

A previous belief that CMT was associated with metatarsus adductus and clubfoot is not supported by the literature.

Typically, children with CMT hold their head laterally flexed to the affected side and rotate their face to the opposite side.

Range of neck movement can initially be normal in infants with CMT. Later, the typical deformity can usually be observed. This gradually progresses as the muscle contracture becomes tighter.

Any degree of restriction should be noted during the examination.

The facial bones and cranium are observed for asymmetry. Any flattening of the skull bones is also noted.

With palpation, a nontender, soft mass of 1 to 2 cm is occasionally found in the lower or middle third of the SCM muscle. With time, the mass changes to a fibrous bundle, and the SCM tendon can then be identified as a tight band that resists correction (FIG 2).

FIG 2 • A nontender, soft mass of 1 to 2 cm can be found in the lower or middle third of the sternocleidomastoid (SCM) muscle within weeks or a few months after delivery. At later ages (usually after 6 to 12 months of age), the mass changes to a fibrous bundle and the SCM tendon then can be identified as a tight band.
The flexible deformity seen in the early stage can be corrected by gentle stretching.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Neuroradiographs
  - Standard cervical spine anteroposterior and lateral views and open-mouth odontoid views are obtained to rule out bony abnormalities such as atlantoaxial instability or fixation, cervical fusion, cervical scoliosis, and odontoid anomalies.
  - At the later phases of the developing deformity, radiographic abnormalities such as asymmetry of the articular facets of the axis, tilt of the odontoid process to the side of the torticollis, and sometimes cervicothoracic scoliosis may be observed.\(^1^,\(^2\)

- Ultrasound examination should be performed in children with a palpable SCM mass to demonstrate the fibrotic lesion within the SCM muscle and to differentiate the mass from other pathologies in the neck such as neoplasms, cysts, and vascular malformations.
  - In a recent study, Tang et al\(^1\) presented their observations with the use of ultrasound for the long-term follow-up of CMT. They noticed that CMT is a polymorphic and dynamic condition rather than a fixed presentation. The alterations of the fibrosis in muscle can affect the type of treatment.

- Hip ultrasonography should be routinely done in patients born with CMT.
  - There is a relatively high incidence of coexistence between CMT and DDH.

- Some investigators have advised MRI to evaluate the muscle for thickening and fibrosis; however, it does not provide additional information. Further, for infants, MRI requires a general anesthetic, with its associated risks.
  - If a posterior fossa tumor is suspected, MRI is indicated.

**DIFFERENTIAL DIAGNOSIS**

- Ophthalmologic torticollis occurs with oculomotor imbalance, which is usually observed after the development of focusing skills (3 months). Ophthalmologic torticollis is caused by a weakness of one of the oculomotor muscles of the eye (typically the superior oblique). This causes a strabismus that can be observed if the head tilt is manually corrected. (This maneuver is useful in providing a diagnosis.) Other causes are strabismus and nystagmus.

- Neurologic causes such as the postural head tilt seen with posterior fossa tumors must be ruled out.
  - Nucci et al,\(^1\) in a multidisciplinary study, reported 25 ocular and 4 neurologic causes in 65 children with abnormal head posture.
  - About 10% of posterior fossa tumors initially present with torticollis.

- The other orthopaedic causes of torticollis include congenital cervical vertebral anomalies (scoliosis, Klippel-Feil syndrome) and atlantoaxial rotational instability.

- Grisel syndrome: torticollis associated with retropharyngeal abscess or post-tonsilllectomy status.

- Neck abscess or inflammatory disorders

- Sandifer syndrome (reflux)

- Neurologic
  - Posterior fossa tumors
  - Dystonia

**NONOPERATIVE MANAGEMENT**

- The initial treatment of CMT is nonoperative and is successful in the vast majority of infants by 1 year of age.

- A program of gentle stretching exercises should include flexion–extension, lateral bending away from the involved side and rotation toward it.

- Stretching exercises can be done by a physical therapist or by the parents with a home program.
  - In our experience, a supervised home program monitored by a physical therapist is the most successful method.
  - Manual stretching should be continued until full neck rotation is achieved.

- In children 1 year of age or less, the plagiocephaly and facial asymmetry usually remodel spontaneously after the child regains full range of motion of the neck.

- Cervical orthoses may be an adjunct and support for children whose lateral head tilt does not resolve with exercises, or for older children who no longer tolerate stretching.

- The duration of the conservative treatment could be longer in children who have SCM tumor at initial presentation.

- The success rate of manual stretching in these patients is lower than those without a SCM tumor.\(^4\)

- Surgery is recommended for recalcitrant deformity when adequate correction is not achieved by 1 year of age.

- Children who present after 1 year of age with or without previous treatment are candidates for surgery if they have:
  - Significant head tilt with tight band or contracture of the SCM muscle

  - Limitation of passive head rotation and lateral flexion by more than 10 to 15 degrees

**SURGICAL MANAGEMENT**

- Surgical intervention is indicated for children who have not responded to nonoperative treatment applied for a minimum of 6 months and for children who present with a significant deformity after 1 year of age.

- The hypothesis is that the sooner correction of the torticollis is achieved, the better the chance for spontaneous correction of the plagiocephaly and facial asymmetry.

- If there is doubt about the diagnosis of CMT, surgery is contraindicated until a workup has been completed because there could be an underlying disorder causing torticollis, such as ocular or neurogenic pathologies.

- The operative techniques described for CMT are based on release or lengthening of the tight and shortened SCM muscle.

- Most commonly preferred procedures include unipolar release, bipolar release with or without Z-plasty lengthening of the sternal head, and the extended procedure for older children and resistant cases.

- Open, percutaneous, and endoscopic techniques have been described for these procedures. We have no experience with endoscopic technique, and we prefer the open approach.

**Authors’ Preferred Treatment**

- For infants, a home stretching program is taught and supervised by a physical therapist for 6 months.

- In children with appropriate surgical indications, bipolar release (with or without Z-plasty lengthening) is carried out.

- In older children with significant deformity, a bipolar release is the first step. Z-plasty may be appropriate in the older children to provide a symmetric appearance postoperatively.
If satisfactory correction is not demonstrated at intraoperative examination, the distal dissection is extended to permit release of the clavicular head and remaining bands.

Preoperative Planning
- Cervical spine radiographs should be reviewed before surgery to look for bony anomalies or cervical scoliosis.
- In fixed deformities, positioning of the head can be difficult for the anesthesiologist. Flexible fiberoptic intubation should then be considered.
- The ear is taped anteriorly and hair around the mastoid process is shaved.

Positioning
- The procedure is performed under general anesthesia in the supine position. A sandbag is placed to elevate the shoulder on the affected side.

Draping should allow the correction to be evaluated by bending the neck. This determines the adequacy of the release intraoperatively.
- The shoulder draping should permit the anesthesiologist to hold the shoulder, which can maximize tension during this test.
- The neck is bent toward the unaffected side and the head is rotated to the affected side so that the SCM muscle is kept under tension and the origin and insertion can be clearly identified.

INCISION AND DISSECTION
- For the release of the distal pole of the SCM muscle, a transverse, 3- to 4-cm-long incision is made 1 cm superior to the clavicle and between the two heads of the SCM muscle (TECH FIG 1).
- The subcutaneous tissue and platysma muscle are divided in the line of incision and the tendon sheaths of the clavicular and sternal heads are exposed.
- For the proximal pole exposure, a 2- to 3-cm horizontal incision is made just distal to the tip of the mastoid process.
- The dissection is carried deeper until the periosteum of the mastoid process is exposed. The insertion of the muscle is then exposed subperiosteally.

TECH FIG 1 • Proximal and distal incisions (dotted lines).

DISTAL UNIPOLAR RELEASE
- Distal unipolar release includes the release of the sternal and sometimes the clavicular heads of the SCM muscle. It may be enough for mild deformities.
- A transverse incision is placed parallel and 1 cm proximal to the clavicle between the clavicular and sternal heads of the SCM.
- An incision that overlies over the clavicle may result in a hypertrophic scar. A higher incision may jeopardize the external jugular vein and may also lead to an unsightly scar.
- Two heads of the SCM muscle are identified as described.
- Surrounding fascia is cleared and the sternal head or both heads are undermined with a curved clamp.
- The muscles are elevated with the help of a clamp and divided using electrocautery (TECH FIG 2).
- Alternatively, the sternal head can be lengthened by Z-plasty.
- The endotracheal tube should be kept at the unaffected side so as not to interfere with the operative field.

TECH FIG 2 • The origin of the muscle is elevated with the help of a clamp and divided using electrocautery. About 5 to 10 mm of muscle–tendon segment is divided to prevent further contracture and fibrous adhesions.
About 5 to 10 mm of the muscle–tendon segment is excised to prevent further contracture and fibrous adhesions.

The adequacy of the release is checked by bending the neck to the contralateral side and rotating it to the ipsilateral side while palpating the area with a fingertip to identify any remaining tight bands. They are completely released.

The incision is closed with subcuticular suture after careful hemostasis.

**BIPOLAR RELEASE (AUTHORS’ PREFERENCE)**

- Bipolar release includes the release of the mastoid insertion of the SCM muscle along with the distal release just described.
- The procedure starts with a distal incision.
- The two heads of the SCM muscle are identified. After undermining the tendons, the curved clamp is left underneath them.
- The curved clamp is left lying superficial to the wound but deep to the tendon. While applying enough tension, ease the proximal exposure and identification of the insertion. The wound is then covered with a moist sponge.
- With the tension applied by the clamp under the tendon at the distal exposure, a safe identification of the origin has been simplified. Further, the limited exposure avoids the important anatomy (TECH FIG 3A).
- Attention is directed to the proximal insertion and the incision is placed as described before.
- The insertion of the muscle is identified anteriorly and posteriorly. Dissection starts subperiosteally from the mastoid process to avoid the facial nerve anteriorly and the anterior branch of the great auricular nerve inferiorly.
- A curved clamp is passed just deep to the tendon to elevate it so it can be sectioned completely (TECH FIG 3B).
- There is no need to resect a segment of muscle at the proximal part.
- After the proximal release is performed, attention is then directed back to the distal incision and distal release is completed as described before.
- Release of the clavicular head with the lengthening of the sternal head by Z-plasty may be appropriate in older children to provide a symmetrical appearance postoperatively (TECH FIG 3C).
- The neck is rotated and bent with the help of the anesthesia team while checking the area with a fingertip to identify any remaining tight bands; they are completely released.
- Both surgical areas are checked to identify if any remaining tight bands or fascial structures are impediment full correction. They are divided carefully.
- Subcutaneous and subcuticular skin closure is then performed after hemostasis.

**TECH FIG 3 • A.** With tension applied to the tendon at the distal exposure, a safe identification of the origin has been simplified. Further, the limited exposure avoids the important anatomy. **B.** A curved clamp is passed just deep to the tendon to elevate it for complete sectioning. **C.** Bipolar release with the lengthening of the sternal head by Z-plasty. (C. Modified from Ferkel RD, Westin GW, Dawson EG, et al. Muscular torticollis: a modified approach. J Bone Joint Surg Am 1983;65:894–890.)
**POSTOPERATIVE CARE**
- Postoperative management includes immobilization of the head and neck in a slightly overcorrected position with a thermoplastic custom-made brace or pinless halo for 3 weeks (FIG 3).
  - The purpose of the brace immobilization is to avoid a habitual posture followed by postoperative scarring. It might also help to reprogram the corrected posture as a norm for the child.
  - The brace is removed in 3 weeks and passive stretching is recommended as well as active strengthening exercises.
  - Exercises are continued at home for 3 to 6 months.

**OUTCOMES**
- Early conservative management is successful in over 90% of children with CMT who are younger than 1 year.\(^{3,4,6}\)
- In resistant cases there is still controversy between unipolar and bipolar release.
- Cheng et al\(^{3,4,5}\) reported excellent results in children operated on at age 6 months to 2 years with unipolar release.
- Canale et al\(^{1}\) found better results after bipolar release, although the difference was not statistically significant.
- Wirth et al\(^{16}\) reported satisfactory results in 48 of 55 patients who had undergone bipolar release, with low recurrence rates (1.8%).

**PEARLS AND PITFALLS**

**Approach**
- The distal pole incision is made about 1 cm superior and parallel to the clavicle.
- Superficial scars just over the clavicle may result in hypertrophic scar and unacceptable cosmesis.
- Incisions close to the midpoint of SCM may compromise the external jugular vein and neurologic structures and may lead to an unacceptable scar.
- To avoid complications, the proximal horizontal incision is placed just distal to the tip of the mastoid process. Applying tension under the tendon distally simplifies safe identification of the insertion.

**Unipolar release**
- Unipolar release is used only in younger patients with mild deformities. Generally, a bipolar approach is better.

**Bipolar release**
- A bipolar release is more likely to avoid residual and recurrent deformity. The surgeon should not hesitate to perform this procedure before 1 year of age in resistant cases (9 to 12 months).
- The SCM tendon is first exposed at the origin in the distal wound. The tendon or tendons are elevated to provide tension; the proximal release is then performed, and finally the distal release is completed.

**COMPLICATIONS**
- Wound breakdown
- Hematoma
- Residual lateral band
- Neurovascular damage
  - Spinal accessory nerve
  - Anterior branch of the great auricular nerve
  - External jugular vein
  - Carotid artery
- Hypertrophic scar

**REFERENCES**
DEFINITION
- The occipitocervical articulation is formed by the occiput, the atlas (C1), and the axis (C2). This functional unit provides a large degree of mobility and range of motion through the strong ligamentous structures and cup-shaped joints.
- Over 50% of the total axial rotation occurs between the first and second vertebrae, while flexion–extension movement predominantly occurs at the occipitoatlantal junction.2
- Excessive movement at this junction due to either bony or ligamentous abnormalities causes instability. A wide variety of pathologies such as genetic and congenital developmental abnormalities, trauma, tumors, and inflammatory and degenerative conditions can lead to upper cervical spine instability.
- Depending on the degree of displacement and spinal canal compromise, cord compression and myelopathy may occur.
- Major instability is usually addressed with surgical occipitocervical or C1–C2 arthrodesis. Since Foerster first described a technique for occipitocervical arthrodesis using fibular strut graft in 1927, several procedures have been reported with variable rates of fusion and techniques of stabilization.
- In this chapter, brief information on upper cervical spine instability is given and general principles of occipitocervical and C1–C2 arthrodesis are discussed. Also our techniques developed for posterior occipitocervical fusion are described in detail.

ANATOMY
- It is important to understand that the pediatric upper cervical spine is not a “miniature model” of the adult spine. The cervical spine approaches adult size and shape by ages 8 to 12, as growth cartilage fuses and vertebral bodies gradually lose their oval or wedge shape and become more rectangular.
- The upper cervical spine has unique development, anatomy, and biomechanics.
- The atlas develops from three ossification centers, a body and two neurocentral arches, which become visible by age 1 year (FIG 1A).
- The neurocentral synchondroses fuse with the body at about 7 years of age and may be mistaken for fractures on radiographs.14
- The axis is derived from five primary ossification centers: the two neural arches or lateral masses; the two halves of the dens; and the body.
- There are two secondary centers: the ossiculum terminale and the inferior ring apophysis (FIG 1B).
- The two halves of the odontoid are generally fused at birth but may persist as two centers, known as the dens bicornis.13
- The dentocentral synchondrosis, which separates the dens from the body, closes between the ages of 5 and 7 (FIG 1B). Until the ossification is complete, it gives the appearance of a “cork in a bottle” on an open-mouth odontoid view.
- The tip of the dens appears at age 3 years and is fused by age 12.
- Occasionally, it remains as a separate ossiculum.11,15
- After skeletal maturity the atlas does not have a body as such, and is shaped like a ring. The flat, cup-shaped articular surface under the occipital condyle allows for flexion, extension, and some bending. The dens articulates with C1 through the dorsal facet of the anterior arch. C1–C2 articulation allows for rotation.2 The vertebral artery passes through the foramen that is located in the transverse processes.
- The ligamentous structure allows for a wide range of motion of the upper cervical spine while maintaining stability. The short ligaments at the base of the skull are as follows (FIG 1C):
  - Tectorial membrane, which is a continuation of the posterior longitudinal ligament that provides considerable support.
  - Cruciate ligament, which includes transfer ligaments, restrains against atlantoaxial anteroposterior translation.
  - Alar and apical ligaments, which run from foramen magnum to the odontoid, act as secondary stabilizers.

PATHOGENESIS
- Fundamentally, upper cervical spine instability can develop from osseous or ligamentous abnormalities resulting from acquired or congenital disorders. As a result of instability, excessive motion and spinal cord compression may occur at the occipitoatlantal and atlantoaxial joint or both.
- In nontraumatic conditions, ligamentous laxity (particularly in the transverse ligament) or abnormalities of the odontoid cause instability.
- In Grisel syndrome, a type of atlantoaxial rotatory displacement, inflammation of the retropharyngeal space, caused by upper respiratory tract infections or by adenotonsillectomy, spreads through the pharyngovertebral veins to the ligaments of the upper cervical spine. This results in impairment of the transverse atlantal ligament and instability.21
- In Down syndrome, the main cause of atlantoaxial instability is the laxity of the transverse ligament, which holds the dens against the posterior border of the anterior arch. Also, malformation of the odontoid can be observed in this condition.9
- Klippel-Feil syndrome is associated with congenital cervical anomalies, such as occipitocervical synostosis, basilar impression, and anomalies of the odontoid, and can be associated with instability, stenosis, or both.
- Odontoid anomalies include aplasia, hypoplasia, duplication, third condyle, persisting ossiculum terminale, and os odontoideum.
- The atlantodental interval (ADI), which is measured from the anterior aspect of the dens to the posterior aspect of the anterior ring of the atlas, increases in atlantoaxial instability. It is a way of assessing the more important space available for the cord. The transverse ligament serves as the first line of defense, maintaining the atlanto–odontoid interval.
- In older children (older than 8 years) and adults, the ADI should be 3 mm or less, while in younger children, the ADI should be 4 mm or less (some consider 4.5 to 5 mm acceptable).12
In children, we consider an ADI of 4 mm or more as evidence of atlantoaxial instability.

NATURAL HISTORY
- Patients with upper cervical instability frequently have other associated pathologic conditions in the occipitocervical region such as spinal stenosis, basilar impression, cervical fusions, occipitalization, or congenital anomalies of the atlas or axis (dens), and central nervous system abnormalities.
- When one encounters one of these conditions, others should be sought also.
- Instability of the upper cervical spine and stenosis often are two major factors in the development of myelopathy.
- Patients who are symptomatic at initial presentation are often at risk for progressive neurologic symptoms. Once cervical myelopathy develops it rarely resolves entirely.
- Paralysis and death are rare but may be encountered in patients with upper cervical spine instability.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Upper cervical spine instability is rare in patients without predisposing conditions or trauma.
- The instability is usually determined in radiographic examination of the children with syndromes or conditions known to have frequent involvement of the musculoskeletal system. An orthopedic surgeon is usually consulted for children with such conditions.
- Clinical presentation can vary because of the associated syndromes and anomalies.
- Patients may present with symptoms such as loss of range of motion, stiffness, mechanical pain of the head or neck, and torticollis.
- It is not uncommon to see patients presenting with neurologic symptoms, which can vary from minor sensory or motor disturbances to established myelopathy. Neurologic symptoms or signs result from mechanical compression of the spinal cord or nerve roots.
- Torticollis may be the presenting symptom of rotatory or postinfectious atlantoaxial instability.
- According to the degree of compression and the affected site of the spinal cord, signs and symptoms can vary. They may include loss of physical endurance, difficulty walking, weakness, and upper motor neuron signs (spasticity, hyperreflexia, clonus, Babinski sign), which can be seen with anterior spinal column involvement.
- Pain deficits and proprioception and vibratory sense deficits can be seen with posterior spinal column involvement.
- Increased nasal resonance may also be observed. It may occur because of the decreased size of the nasopharynx resulting from anterior displacement of the atlas.
- Vertebral artery distortion and insufficiency may lead to bizarre symptoms such as syncopal episodes, sudden postural collapse without unconsciousness, change in behavior, dizziness, and seizures.
- In cerebellar involvement nystagmus, ataxia and incoordination are the common findings.
- Neurogenic bladder and bowel, cranial nerve involvement, paraplegia, hemiplegia, and quadriplegia should be kept in mind; sometimes the patient presents with only one of these findings.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standard radiographs include anteroposterior, open-mouth odontoid, and lateral (neutral and flexion-extension) cervical spine views.
- Instability can be identified on the lateral flexion-extension view. Atlantoaxial instability is diagnosed on the basis of an increased ADI (FIG 2A).
- In children older than 8 years and in adults, the ADI should be 3 mm or less, while in younger children the ADI should be 4 mm or less (some consider 4.5 to 5 mm acceptable).\(^\text{12}\)
- In children, we consider an ADI of 4 mm or more as evidence of atlantoaxial instability. This measurement does not always correlate with the degree of brainstem or cord compression (as seen on MRI), however. An asymptomatic patient may have instability.

- Space available for the spinal cord (SAC) is measured from the posterior border of the dens to the anterior border of the posterior tubercle. According to Steel’s rule of thirds,\(^\text{17}\) SAC should be about one third of the diameter of the ring of atlas (FIG 2A).
- This safe zone allows for some degree of pathologic displacement. Displacement of more than one third of the diameter causes cord compression.
- This measurement directly describes the space available for the spinal cord, which is highly associated with the neurologic involvement.

- The relationship between the foramen magnum, atlas, and odontoid can be determined in lateral radiographs.
- The ADI is measured from the anterior aspect of the dens to the posterior aspect of the anterior ring of the atlas (FIG 2A).
- In older children (older than 8 years) and adults, the ADI should be 3 mm or less.
- In younger children, the ADI should be 4 mm or less (some consider 4.5 to 5 mm acceptable).
- The line of McRae connects the anterior rim of the foramen magnum to the posterior rim (FIG 2A).
- The upper tip of the odontoid should normally be 1 cm below the anterior margin of the foramen magnum.
- If the effective sagittal diameter of the canal (length of the line) is less than 19 mm, neurologic symptoms occur.
- The line of Chamberlain is drawn from the posterior margin of the odontoid to the posterior margin of the foramen magnum (see FIG 2).
- The tip of the odontoid should be 6 mm below this line. It bisects the line in basilar invagination. However, determination of the landmarks can be difficult on plain radiographs.
- The McGregor line is drawn from the most caudal point of the occipital projection to the posterior edge of the hard plate (FIG 2A).
- This line is one of the best for detecting basilar impression because the osseous landmarks can usually be seen at all ages. If the tip of the odontoid process lies more than 4.5 mm above this line, the finding is consistent with basilar impression.
- The line of Wackenheim is drawn parallel to the posterior surface of the clivus (FIG 2A).
- The inferior extension of the line should be in touch with the posterior tip of the odontoid. In basilar invagination it is over that line.
- The Wiesel-Rothman line is drawn connecting the anterior and posterior arches of the atlas. Two lines are drawn perpendicular to this line, one through the basion and the other through the posterior margin of the anterior arch of the atlas (FIG 2B).
- A change in the distance (\(x\)) between these lines of more than 1 mm in flexion and extension indicates increased abnormal translational motion.
- The ratio of Power is calculated from a line drawn from the basion to the posterior arch of the atlas and a second line from

FIG 2 • A. Lateral craniometry of the cranio-vertebral junction with landmarks, commonly used lines, and methods for examining the relationship between the atlas, odontoid, and foramen magnum and measuring the space available for the spinal cord (SAC). The atlanto-dental interval (ADI) is measured from the anterior aspect of the dens to the posterior aspect of the anterior ring of the atlas. The McRae line connects the anterior rim of the foramen magnum to the posterior rim. The Chamberlain line is drawn from the posterior margin of the dens to the posterior aspect of the posterior margin of the foramen magnum. The McGregor line is drawn from the most caudal point of the occipital projection to the posterior edge of the hard palate. The Wackenheim line is drawn parallel to the posterior surface of the clivus. B. Method for calculating the Wiesel-Rothman line for atlanto-occipital instability. A line is drawn connecting the anterior and posterior arches of the atlas (line 1–2). Two lines are drawn perpendicular to this line, one through the basion and the other through the posterior margin of the anterior arch of the atlas (line 3). A change in the distance (\(x\)) between these lines of more than 1 mm in flexion and extension indicates increased abnormal translational motion. C. Lines used to calculate the Power ratio. A line is drawn from the basion (B) to the posterior arch of the atlas (O) and a second line from the opisthion (O) to the anterior arch (A) of the atlas. The length of the first line is divided by the length of the second. (Adapted from Copley LA, Dormans JP. Cervical spine disorders in infants and children. J Am Acad Orthop Surg 1998;6:204–214.)
the opisthion to the anterior arch of the atlas (FIG 2C). The length of the first line is divided by the length of the second.
- A ratio of less than 1.0 is normal.
- A ratio of 1.0 or more is abnormal and is diagnostic of anterior occipitoatlantal dislocation.
- MRI is useful to identify pathologic changes at the dura mater and spinal cord as well as additional soft tissue pathologies.
- Functional MRI scans performed in flexion and extension can be used to assess dynamic brainstem or cord compression.
- CT scan can provide additional information regarding the bony anomalies.
- In atlantoaxial rotational displacement, pathoanatomy is determined by fine-cut dynamic CT scan with left-right rotation of the head.

DIFFERENTIAL DIAGNOSIS
- Pseudosubluxation
- Os odontoideum
- Congenital muscular torticollis
- Ankylosing spondylitis

NONOPERATIVE MANAGEMENT
- Children with known risk of upper cervical instability should be evaluated carefully. Especially patients with congenital syndromes associated with upper cervical spine instability should have periodic clinical and radiographic examinations until maturity.\(^\text{19}\)
- Upper cervical spine radiographs including anteroposterior (AP), lateral (neutral and flexion-extension views), and open-mouth odontoid views are obtained periodically to assess and detect any trends and changes.
- Patients and parents should be educated about the diagnosis and natural history of the disorder and encouraged to report any symptoms as soon as they occur.
- Because of bone and ligament abnormalities, patients with upper cervical spine instability have a greater risk of spinal cord injury even with minor trauma and even when they are asymptomatic.
- As previously described, periodic observation should be done and if any progression is noticed, the patient should be prepared for appropriate surgical stabilization when indicated.
- In children we consider an ADI of 4 mm or more as evidence of atlantoaxial instability. Documented significant instability at the atlanto-occipital or atlantoaxial joints is an indication for posterior arthrodesis of occiput–C2 and C1–C2 arthrodesis, respectively.
- In some congenital disorders such as Morquio syndrome, progression of the instability is frequent; in these cases prophylactic fusion should be considered before neurologic symptoms occur.\(^\text{19}\)
- However, in Down syndrome, the patients with instability are usually asymptomatic and in most cases signs and symptoms progress slowly. Restriction of high-risk activities usually is appropriate. If the clinical symptoms persist or neurologic symptoms are starting to occur in the setting of significant instability, surgical treatment is indicated.\(^\text{9,16}\)
- Children with congenital fusion of cervical vertebrae (mostly in Klippel-Feil syndrome) should be restricted from high-risk sports. Patients with progressive symptomatic seg-

mental instability or neurologic compromise are candidates for surgical stabilization.\(^\text{18}\)

SURGICAL MANAGEMENT
- The main indication for the posterior occiput–C1 or C1–C2 arthrodesis is instability of the atlanto-occipital or atlantoaxial joint.
- For occipitoatlantal instability and instability with congenital or acquired (because of removal of tumor or laminectomy) defects of posterior elements, we developed two techniques of occipitocervical arthrodesis at our institution.
- Rib graft technique
- Iliac graft technique
- Many techniques of atlantoaxial fusion using cables, transarticular screws, plates, and bone graft materials have been described. For isolated atlantoaxial instability, we commonly prefer the Gallie technique, the Mah modified Gallie technique, and the Brooks sublaminar wire technique.

Preoperative Planning
- Plain radiographs and CT scans are reviewed and any osseous findings noted.
- MRI evaluation for the spinal cord compression is recommended.
- An appropriate halo ring is measured for the patient. Somatosensory evoked potentials, transcortical motor-evoked potentials, and electromyography are the preferred neurologic monitoring modalities.
- Flexible fiberoptic intubation with manual in-line axial stabilization should be considered to minimize cervical motion during intubation maneuvers.

Positioning
- After induction of general anesthesia in the supine position, a halo ring is applied, and the patient is carefully turned to the prone position.
- The halo device is fixed to the Mayfield positioning device, which is securely fixed to the operating table (FIG 3).
- Lateral fluoroscopy or radiography should be done before starting the procedure to confirm the alignment of the occiput and cervical spine.
- Donor sites (rib or ilium) are also prepared for graft harvesting.

Approach
- The posterior midline incision is made from the occiput to the intended distal fusion site (usually C2) for occipitocervical arthrodesis.
- The paraspinal muscles are elevated with a Cobb elevator and retracted laterally. Excessive lateral dissection should be avoided to prevent any damage to the vertebral artery, which runs in a serpentine course in relationship to the C2 vertebra.
- For occipitocervical arthrodesis, the dissection is carried proximally to the occipital protuberance and distally to the level planned to include the fusion.
- For atlantoaxial arthrodesis, the dissection is started from the lower occiput and the surgeon identifies the posterior arch of the atlas, the bifid spinous processes, and the lamina of the axis.
- The surgical exposure of vertebra is limited up to the intended level of fusion to prevent unintentional inclusion of the adjacent level in the fusion mass.
OCCIPITOCERVICAL ARTHRODESIS WITH ILIAC GRAFT

- At the level below the transverse sinus, four transverse-oriented holes are drilled through both cortices of the occiput with a high-speed diamond drill.\(^7\)
  - The holes are aligned transversely with two on each side of the midline. At least 1 cm of intact bone should be left between the holes to prevent wire pull-out through the skull (TECH FIG 1A).
- Surgical loupes and a headlamp are recommended for this procedure.
- Using a high-speed diamond burr, the surgeon makes a transverse-oriented trough into the base of the occiput to fit the rectangular superior part of the iliac autograft.
- A single corticocancellous autograft (3 × 4 cm) is harvested through an oblique incision over the posterior superior iliac spine.
- A rectangular graft is taken. The surgeon creates a notch in the inferior base of the graft to be suitable for the base of the spinous process of the second or third vertebra (TECH FIG 1B).
- 16- or 18-gauge wire is passed through the burr holes on each side of the midline and the wire is looped on itself (TECH FIG 1C,D).

- A sublaminar wire is placed under the ring of C2 or C3 (or passed through the base of the spinous process, if structurally sufficient, or if there is canal stenosis).
- The left side of the graft accepts the left end of the wire and the right end of the graft accepts the right end of the wire (TECH FIG 1E).
- The edges of the graft are contoured to fit appropriately into the occipital trough and around the base of the spinous process (TECH FIG 1F).
- The wires are tightened over the graft in figure 8 shape. After satisfactory tightening the edges of the wire are cut and bent away from skin (TECH FIG 1G,H).
- Intraoperative fluoroscopy or radiography is used to confirm the alignment of the occiput and cervical spine, stability, and the position of the graft and wires.
- The graft should be structurally stable at the end of the procedure.
- Flexion-extension of the halo frame, better contouring of the graft, and appropriate tightening of the wires can be used to make adjustments in reduction and alignment.
TECH FIG 1 (continued) C. A Luque wire is passed through the occipital burr hole and another wire is passed sublaminarly under the arch of C2 or through the base of the C2 spinous process. D. Occipital wire is looped on itself. E. Schematic drawing showing occipital wire looped on itself and the wire passed through the base of the C2 spinous process. F. Graft (arrow) placed between the occiput and C2. G. The wires are tightened over the graft in a figure 8 shape, twisted, and cut. H. Schematic drawing showing the graft placement and securing with wires.

OCCIPITOCERVICAL ARTHRODESIS WITH RIB GRAFT

- An oblique incision overlying the posterior rib allows for adequate exposure.3
  - The muscle fibers are separated and dissection is carried down to the periosteum of the rib.
- Adequate rib is exposed and cut.
  - The size of the rib graft is greater than the area to be fused because part of the rib is used as morcelized graft.
  - Using a rib cutter, the graft is cut distally and proximally and removed (TECH FIG 2A).
- Irrigation fluid is placed in the surgical site and positive pressure applied to check for pleural leaks.
- If a pleural tear is detected, air can be removed from the chest cavity by using a red rubber tube and suction.
- A larger leak may require placement of a thoracostomy drainage tube.
  - In all patients, a chest radiograph should be taken after rib harvest to rule out pneumothorax.
- Two full-thickness structural grafts are prepared to fit the arthrodesis site.
  - The rib grafts can span large defects and fit nicely into large or abnormally shaped skull, and we find this best for young infants.
- 16- or 18-gauge wire is looped through the burr holes on each side of the midline (see TECH FIG 1C).
  - The burr holes are drilled and aligned similarly to the ones described for the iliac graft technique.
- There is no need to create a groove at the base of the occiput.
  - Braided cable or no. 5 Mersilene sutures may be used instead of wire.
  - With Mersilene sutures there is a reduced risk of cutting out in thin bone of poor quality.
- After this, purchase of two wires is made to the posterior elements of most caudal vertebra on each side of the midline by sublaminar wiring.
  - Suitable grafts on either side are then secured to the occiput and lamina of the most caudal vertebra by wires.
  - The stability of the grafts is checked under radiographic control and the wires are then crimped and cut (TECH FIG 2B,C).
- Adjustments are made by flexion–extension of the halo frame, contouring of the graft, and appropriate tightening of the wire.
  - Intraoperative radiographs are obtained to confirm acceptable reduction, alignment, and placement of the graft.
- For both techniques, morcellized autograft is packed into the arthrodesis site. The wound is closed in layers.
  - The halo vest is worn for 8 to 12 weeks after both techniques to maintain postoperative stability (TECH FIG 2D,E).
Chapter 55  POSTERIOR CERVICAL ARTHRODESSES: OCCIPUT–C2 AND C1–C2

POSTERIOR C1–C2 ARTHRODESIS

- The preoperative planning is similar to that for the occipitocervical arthrodesis described earlier in the section.

Gallie Technique

- After exposing the posterior arch of the atlas and spinous process of the axis, the two free ends of a single 16- or 18-gauge wire are passed beneath the posterior arch of the atlas from a superior-to-inferior direction.\textsuperscript{10}
- The free ends are passed beneath the posterior arch and are brought around superiorly to loop on themselves.
- A rectangular corticocancellous autograft is harvested from the posterior iliac spine.
  - A notch is created at the distal part of the graft. This part will be placed across the spinous process of the axis.
- The notched graft is placed between the posterior portion of the arch of C1 and the posterior spinous process of C2.
- Now the free ends of the looped wire are brought down over the graft and passed below the spinous process.
- The free ends of the wire are tightened and twisted over the graft (TECH FIG 3).

- Morcellized bone grafts may be packed into the fusion area to add additional support.
- Intraoperative fluoroscopy is necessary to check for satisfactory reduction and alignment of C1–C2.

Mah Modified Gallie Technique

- In 1989, Mah described a modification of the Gallie technique.\textsuperscript{13}
- All the steps of the Mah technique are similar to the Gallie technique, except that a threaded Kirschner wire is placed through the spinous process of the C2 and both ends of the Kirschner wire are cut, leaving about 2.5 cm of the total wire.
- The free ends of the looped wire are brought down below the free ends of the threaded Kirschner wire (TECH FIG 4).
- The free ends of the wire are tightened, secured, and crimped over the graft.

TECH FIG 2 • A. Adequate rib is exposed and harvested. B. Rib graft is placed and fixed with braided cables and #5 Mersilene suture. C. Schematic drawing showing the rib graft fixed with wire. D, E. A 5-year-old-boy immobilized with a halo vest postoperatively. (C: Adapted from Cohen MW, Drummond DS, Flynn JM, et al. A technique of occipitocervical arthrodesis in children using autologous rib grafts. Spine 2001;26:825–829.)

TECH FIG 3 • Gallie technique for atlantoaxial arthrodesis.

TECH FIG 4 • Mah modified Gallie technique for atlantoaxial arthrodesis.
Brooks Technique

- A standard posterior midline incision is used to expose the posterior arch of C1 and the lamina of C2.  
- Two sublaminar wires are passed under both C1 and C2 laminas, one on each side of the midline.  
- Unlike the Gallie technique, two separate corticocancelous grafts are required in this technique. A single rectangular iliac crest graft is harvested; it can be separated into two equal parts.  
- Each iliac crest graft is cut into a trapezoid-like shape (one end is narrower than the other) so that they can be wedged between the C1 and C2 posterior arches (TECH FIG 5A).  
- The grafts are snugly wedged into place. The wires are then tightened around the grafts, twisted, and cut (TECH FIG 5B).

TECH FIG 5 • Brooks arthrodesis. A. Lateral view demonstrating a wedge-shaped graft between the spinous processes to prevent hyperextension. The graft is shaped so that one end is narrower than the other to achieve a good fit. B. The grafts are snugly wedged between the C1 and C2 posterior arches, and the wires are tightened around the grafts.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Approach</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Excessive lateral dissection should be avoided so as not to damage the vertebral arteries and major venous junctions.</td>
<td></td>
</tr>
<tr>
<td>In the case of an open posterior arch, meticulous and blunt dissection should be used to keep from injuring the dura mater and the cord.</td>
<td></td>
</tr>
<tr>
<td>Excessive dissection and extended dissection time are avoided.</td>
<td></td>
</tr>
<tr>
<td>This may increase the risk of inadvertent extension of the fusion mass.</td>
<td></td>

<thead>
<tr>
<th>Occipitocervical arthrodesis with iliac graft technique</th>
<th>This technique is associated with stable internal fixation and high fusion rates.</th>
</tr>
</thead>
<tbody>
<tr>
<td>A large occipitocervical segment can be spanned.</td>
<td></td>
</tr>
<tr>
<td>Rib grafts can be shaped easily because of their elastic structure.</td>
<td></td>
</tr>
<tr>
<td>This technique is best for infants, small children, or patients with an abnormally shaped skull.</td>
<td></td>
</tr>
</tbody>
</table>

| C1–C2 arthrodesis with Gallie technique |  |
| This procedure is more suitable in older children who have a competent spinous process. |  |
| It is not always necessary to pass wire or cable underneath the lamina of the axis. |  |
| This technique provides good stability in flexion and extension but may be insufficient in rotational maneuvers. |  |

| C1–C2 arthrodesis with Mah modification | The wire can securely hold behind an insufficiently ossified spinous process with the help of a transverse Kirschner wire. |
| C1–C2 arthrodesis with Brooks technique | This technique provides more rotational stability than the Gallie technique. |
| Disadvantages include the need to pass bilateral sublaminar cables beneath both C1 and C2. |

POSTOPERATIVE CARE

- Postoperative management includes halo vest immobilization for 8 to 12 weeks.  
- Using a standardized method of halo application reduces the rate of complications associated with halo use in children.  
- The rate of pin-track infection with prolonged use of a halo device in children is similar to that in adults. Particular care should be taken to keep the pin-track sites clean.  
- Short-term antibiotic treatment is usually satisfactory in decreasing inflammation at the pin site.  
- When a bony union is documented radiographically, the halo device is removed.  
- Patients can gradually return their daily activities.  
- Special care should be taken to avoid excessive flexion or extension of the neck.  
- Long-term follow-up is necessary for evaluation of potentially progressing junctional instability below the level of fusion.  
- The additional stress placed on the adjacent vertebrae below the level of fusion may result in instability with time.
OUTCOMES

- The senior author (JPD) presented results of the CHOP technique for occipitocervical arthrodesis in 38 children with more than 2 years of follow-up.20
- Thirty-four patients were treated with iliac crest autograft and posterior wiring, or with rib autograft and posterior wiring, and the remaining four with Luque contoured rod and autograft.
- Thirty-four patients had bony union, three patients had fibrous union, and one patient had nonunion.
- Ninety-seven percent of the patients (37 children) showed baseline or improved neurologic status at the most recent follow-up.
- Complications included:
  - Superficial infection treated with oral antibiotics (three patients)
  - Postoperative pneumonia (one patient)
  - Pin-tract infection: most of the patients treated with a halo ring had superficial pin-site infection. All but two patients were treated with oral antibiotics. One patient required intravenous antibiotics and the other required a pin change.
- In 11 patients (29%), we had a distal extension of the fusion mass, seven patients had fusion at one additional level, and four patients had fusion at two additional levels.

COMPLICATIONS

- Graft or wire breakage
- Nonunion, insufficient fusion
- Additional fusion levels and loss of motion
- Junctional instability distal to the fusion mass
- Infection
- Deep wound infection
- Meningitis
- Pin-tract infections (halo)
- Neurologic injury
- Donor site morbidity

REFERENCES

**DEFINITION**

- Scoliosis is a three-dimensional deformity of the spine and rib cage.
- The hallmark of scoliotic spines is curvature in the coronal plane along with abnormal curvature in the sagittal plane (eg, lordoscoliosis in adolescent idiopathic scoliosis) as well as abnormal vertebral rotation in the transverse plane.
- A Cobb angle measurement of greater than 10 degrees distinguishes minor spine asymmetry from true scoliosis.
- The posterior approach to the thoracic and lumbar spine takes advantage of the segmental innervation of the posterior spinal muscles to obtain an internervous and intermuscular plane to provide access to the posterior elements of the spine.
- The posterior approach is the most commonly used route for spinal fusion and instrumentation in the scoliotic spine.

**ANATOMY**

- Surface landmarks in the prone position:
  - The vertebra prominens (C7) is typically the most prominent bony structure palpated at the base of the neck.
  - The superior angle of the scapula is at the level of the T3 spinous process.
  - The scapular spine is at the level of the T4 spinous process.
  - The inferior angle of the scapula is at the level of the T7 spinous process.
  - With the patient in the prone position, the iliac crests are palpated with the fingers and the thumbs brought together at the midline, where they typically overlie the L4–5 interspace.
  - The posterior superior iliac spines are at the level of the L5-S1 interspace.
- Posterior spinal musculature is divided into superficial and deep layers. The superficial layer, also known as the erector spinae, is composed of the iliocostalis, longissimus, and sacrospinalis muscles. The deep layer consists of the short rotators (multifidus and rotatores) as well as the intertransversarii and interspinous muscles (FIG 1A,8).
- Segmental innervation of spinal musculature
  - Provided by the dorsal rami of the thoracolumbar nerve roots
- Segmental blood supply
  - The posterior intercostal arteries branch from the aorta and subsequently send a dorsal branch posteriorly to the spinal musculature. On its way past the neural foramina, the spinal artery branches off and is sent through the foramina. The spinal artery then divides into anterior and posterior radicular branches within the spinal canal, ultimately supplying the anterior and posterior spinal arteries. Care should be taken to cauterize the branches that lie adjacent to the lateral aspect of the facet (FIG 1C).
- In the scoliotic spine there is rotation of the vertebral bodies in the transverse plane with the spinous processes rotating toward the concavity of the curve.

**PATHOGENESIS**

- Idiopathic
- Congenital
- Failure of formation or segmentation of vertebral precursors leading to asymmetric vertebral growth with subsequent abnormal curvature
- Neuromuscular
- Variety of etiologies, such as cerebral palsy, muscular dystrophy, polio, spinal muscular atrophy, and myelomeningocele
- Related to an inability to provide muscular support to the spinal column

**NATURAL HISTORY**

**Idiopathic**

- Infantile (0 to 3 years of age)
- Less than 1% of all cases of idiopathic scoliosis
- More common in boys
- Left thoracic curves predominate
- Most resolve spontaneously
- Juvenile (3 to 10 years of age)
- 8% to 16% of all cases of idiopathic scoliosis
- More even female:male ratio
- Bracing may correct some curves
- Curves of more than 30 degrees usually progress to surgery
- Adolescent (10 to 18 years of age)
- Most common form of idiopathic scoliosis
- Etiology and pathogenesis are not well understood
- Family history is positive in 30% of cases but does not predict curve magnitude or progression.
- More common in girls. The female:male ratio is 1.4:1 for curves 11 to 20 degrees and increases to 5:1 for curves greater than 20 degrees.
- Curves have the greatest chance of progression in the period of peak growth velocity leading up to skeletal maturity (prior to menses in females), after which the potential decreases significantly.
- Scoliotic curves measuring less than 20 degrees are at lower risk for progression.
- Scoliotic curves measuring greater than 50 degrees are at higher risk for further progression during adult life (with a percentage of these progressing at a rate of about one degree per year).
- There are no significant differences in the prevalence of back pain between adults with scoliotic spines and the general population.
- Scoliotic curves measuring greater than 100 degrees have an increased prevalence of cardiopulmonary compromise (eg, cor pulmonale, restrictive lung disease).
### Congenital
- Severity of deformity related to type and location of anomaly
- Highest chance of curve progression with unilateral unsegmented bar with contralateral hemivertebrae (nearly 100%), followed by a lone unilateral unsegmented bar, double convex hemivertebrae, single convex hemivertebrae, and finally the block vertebrae\(^3\)

### Neuromuscular
- Most curves are progressive and are more difficult to manage nonoperatively.
- Curves can cause pelvic obliquity and sitting problems in nonambulatory individuals.

#### PATIENT HISTORY AND PHYSICAL FINDINGS
- Complete history, including age at onset, timing of growth spurts, menses, presence of pain, family history of scoliosis, nerve, or muscle diseases
- A complete examination is important to obtain a diagnosis because certain etiologies can predispose the patient to increased operative risk (eg, cardiac abnormalities in patients with Marfan syndrome).

- The skin is inspected for café-au-lait spots, the axilla for freckling, and the lumbar area for sinus tracts, hairy patches, or dimples. Axillary freckling and multiple café-au-lait spots are associated with neurofibromatosis. Sinus tracts, hairy patches, or dimples in the lumbar area are associated with intraspinal anomaly.
- The Adams forward bending test detects curves by physical examination. Abnormalities in vertebral rotation become apparent as an asymmetrical rib hump, prominence, or fullness, leading to possible identification of patients at risk for having scoliosis.
- Any shoulder or scapular asymmetry is noted. It is important to point out to parents that this is not always corrected by surgery.
- Pelvic obliquity can indicate a possible leg-length discrepancy that can mimic a lumbar scoliosis.
- Trunk shift and sagittal profile are noted; these indicate coronal balance and sagittal balance, respectively.
determine the degree of scoliosis, to identify any skeletal abnormalities (eg, hemivertebra), and to evaluate overall alignment.

- PA views are obtained to decrease exposure of sensitive breast tissue to ionizing radiation in girls.
- Side-bending supine views of the thoracolumbar spine are useful to determine the flexibility of the primary and secondary curves. This information is useful during preoperative planning in choosing fusion levels and determining the approach.
- Risser staging system for gauging skeletal maturity (FIG 2)
  - Ossification of the iliac apophyses proceeds along the iliac crest from the anterior superior iliac spine to the posterior superior iliac spine. When ossification is complete, fusion of the apophysis to the iliac crest occurs.
  - Risser 0 = no ossification
  - Risser 1 = 25% excursion
  - Risser 2 = 50% excursion
  - Risser 3 = 75% excursion
  - Risser 4 = 100% excursion
  - Risser 5 = fusion of iliac apophysis to the iliac crest
- In girls, the end of spinal growth corresponds to Risser stage 4.
- In boys, spinal growth can occur after Risser stage 4 and is less well defined.
- MRI should be obtained for patients with an onset before age 10 years, left thoracic curves, kyphoscoliotic curves, or rapidly progressive curves; patients with moderate to severe back pain; patients with congenital or neuromuscular scoliosis; and patients with abnormal findings on the physical examination.

**DIFFERENTIAL DIAGNOSIS**

- Scoliosis
- Idiopathic
- Congenital
- Neuromuscular
- Limb-length discrepancy
- Osteoid osteoma
- Sprengel deformity

**NONOPERATIVE MANAGEMENT**

- Observation for progression for curves of 0 to 20 degrees. Patients are followed with serial clinical and radiographic examinations.
- Bracing for progressive curves of 20 to 40 degrees if the patient is skeletally immature. Braces cannot correct curves; their purpose is to prevent curve progression.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- Preoperative radiographs with supine side-bending films are obtained to determine fusion levels according to the Lenke criteria.
- Cobb angles (FIG 3A)
  - Quantitates the degree of curvature
  - Method
    - Determine apex of curve to be measured.
    - Select the most tilted vertebra above the apex of the curve and draw a line along the top of the vertebral endplate.
    - Select the most tilted vertebra below the apex of the curve and draw a line along the bottom of the vertebral endplate.
- Drop perpendicular lines to these previous two lines.
- The angle subtended by the two lines is the Cobb angle.
- The intraobserver intrinsic error in Cobb angle measurements is about 5%; interobserver validity is about 7%.
- Center sacral vertical line (FIG 3B)
  - Used to help determine distal extent of fusion
  - The vertebral body most closely bisected by the center sacral line is the stable vertebra.
- Fusion is usually extended to the stable vertebra or the one immediately cephalad.

Positioning
- Patient is intubated in the supine position on the stretcher.
- Neurologic monitoring leads are placed cranially, on the intercostal and abdominal musculature, and on all four extremities.
- Multiple large-bore intravenous access is obtained for fluid management and an arterial line is placed for intraoperative blood pressure monitoring.
- The patient is transferred to the prone position on a well-padded operating room table such as a Jackson frame (Orthopaedic Systems, Union City, CA).
- Care should be given to the degree of hip flexion-extension, as this can affect the amount of lordosis in the lumbar spine.
- Bolsters underneath the chest and anterior superior iliac spines prevent abdominal compression and allow epidural venous return, thus decreasing epidural bleeding.

INCISION
- A Bovie electrocautery cord is centered over the back using the vertebra prominens and the gluteal crease, and the line for the straight midline back incision is marked (TECH FIG 1A).
- Bupivacaine (0.25%) with 1:200,000 epinephrine may be injected along the course of the incision for local anesthesia and hemostasis (TECH FIG 1B).
- The skin is sharply incised with a no. 10 blade scalpel and electrocautery is then used to dissect through the subcutaneous fat until the thoracolumbar fascia is reached.
- Weitlaner retractors are placed.
- The spinous processes are identified via palpation (TECH FIG 1C).
Electrocautery is used to dissect through the thoracolumbar fascia at the tips of adjacent spinous processes (TECH FIG 1D,E).

These incisions are connected (TECH FIG 1F).

This proceeds throughout the extent of the incision. Care is taken at the cephalad and caudal aspects of the dissection to leave the interspinous ligaments intact.

**SUBPERIOSTEAL DISSECTION**

- Dissection then proceeds subperiosteally.
- In skeletally immature individuals, the apophyses of the spinous processes are further dissected with a Cobb elevator (TECH FIG 2A).
- Electrocautery is used to advance the dissection deep along the spinous processes until the laminae are reached and the retractors are repositioned (TECH FIG 2B).
- In the thoracic spine, dissection proceeds until the tip of the transverse process is fully exposed.
- In the lumbar spine, dissection proceeds until the facet joint, pars interarticularis, and transverse process are exposed.
- At this point the spine is instrumented.
CLOSED

POSTOPERATIVE CARE

No postoperative immobilization is required with multisegmental constructs.

Postoperative restrictions include limitations with lifting, bending, and twisting.

It is important to maintain mean arterial blood pressure above 70 mm Hg overnight and hemoglobin above 10 g/dL to maintain spinal cord perfusion.

Intravenous antibiotics are maintained for 48 hours postoperatively.

Neurovascular checks are made every 2 hours for the first 8 hours, then every 8 hours.

Diet is advanced as tolerated.

Patient-controlled analgesia is used for appropriate patients. Continuous narcotic infusion with demand for the first 24 hours is followed by oral pain medications when tolerating diet.

A 4-day hospital course is typical.

Activity is increased based on the degree of fusion.

OUTCOMES

With meticulous attention to detail with regard to instrumentation and fusion techniques, excellent outcomes in terms of straightening and fusion of the scoliotic spine can be expected.

Long-term outcomes are variable and depend on the underlying diagnosis and the extent of retained spinal mobility.

COMPLICATIONS

Early or late infection: less than 5%

Wound dehiscence

Hematoma

Instrumentation failure

Pseudarthrosis: 1% to 12% depending on type of fusion and method of diagnosis

Neurologic injury

Spinal cord injuries: consider initiating steroid protocol

Nerve root injuries

Wrong-level surgery

REFERENCES

DEFINITION
- Reduction of scoliotic spinal deformity via posterior spinal fusion with instrumentation allows for improvement of the cosmetic appearance of the child or adolescent with scoliosis and prevents curve progression. The goal is to balance these advantages with the inherent risks of instrumentation and reduction maneuvers.
- Instrumentation provides an internal construct holding the spine in its corrected position until spinal fusion is achieved (about 6 months) and obviates the need for postoperative immobilization. A Cobb angle measurement greater than 10 degrees distinguishes minor spine asymmetry from true scoliosis.
- Segmental instrumentation with hooks and pedicle screws provides multiple fixation points, allowing for three-dimensional correction of the scoliotic spine.
- Instrumentation is introduced after posterior exposure of the thoracic or lumbar spine (see Chap. PE-56).

ANATOMY
- A thorough knowledge of scoliotic spinal anatomy is critical for the safe placement of instrumentation.
- In the scoliotic spine there is rotation of the vertebral bodies in the transverse plane, with the spinous processes rotating toward the concavity of the curve.
- Anatomy of the posterior elements
  - In the scoliotic spine, the pedicles on the concave side are narrower than those on the convexity, especially at the apex of the curve (FIG 1A).12
  - The intervertebral foramina in the thoracic spine are larger and deeper than in any other region of the spine, with the exiting nerve root occupying less than 25% of the foramen and coursing through its midportion.
  - Lumbar nerve roots pass adjacent to the inferomedial aspect of the pedicle and lie superior within the foramina.
- Scoliotic deformity affects not only the bony anatomy but also the relationship of the spine to the adjacent soft tissue elements.
  - The aorta is posterolateral to its normal position, putting it at risk for injury with left-sided lateral pedicular breaches (FIG 1B).
  - The spinal cord hugs the concavity of the curve such that the width of the epidural space is less than 1 mm at the thoracic apical vertebral levels on the concave side; it is 3 to 5 mm on the convex side.8

Thoracic Spine Anatomy
- The thoracic facets are more coronally oriented in comparison to the more sagittally oriented lumbar facets.
- Pedicle anatomy for placement of pedicle screws

Dimensions
- In scoliotic spines, average thoracic pedicle length (distance from the posterior cortical starting point to the posterior longitudinal ligament in line with the axis of the pedicle) is 16 to 22 mm.
- Average thoracic cord length (distance from the posterior cortical starting point to the anterior vertebral cortex in line with the axis of the pedicle) is 34 to 52 mm; it is typically greater on the concavity.
- Coronal anatomy
  - In the scoliotic spine, the medial wall is two to three times thicker than the lateral wall at all thoracic levels. This may be why most screw-related pedicle fractures occur laterally.
• The coronal anatomy of the thoracic pedicle varies, moving from anterior to posterior. The likelihood of pedicle wall breach is greatest midway between the lamina and body with placement of screws.
• Pedicle width decreases from T1 to T4 and then gradually increases to T12, while pedicle height and length tend to increase from T1 to T12.
• Main pedicle diameter is 4 to 6 mm in thoracic scoliosis.
• Endosteal pedicle width in the apical region of the thoracic spine measures 2.5 to 4.2 mm on the concavity of the curve and 4.1 to 5.0 mm on the convexity of the curve.
• In the thoracic spine, transverse processes do not align with the pedicle in the axial plane: they are rostral to the pedicle in the upper thoracic spine and caudal to the pedicle in the lower thoracic spine (crossover occurs at T6–7).
• Transverse orientation
  • T12 pedicles are perpendicular to the floor in the transverse plane.
  • T1 pedicles subtend an angle of about 25 to 30 degrees with the midline in the transverse plane.
  • Thoracic pedicles progressively angle outward in the transverse plane, proceeding superiorly from T12 to T1.
• Thoracic pedicle screw starting points
  • As one proceeds proximally from T12 there is a trend toward a more medial and cephalad pedicle starting point as one proceeds proximally from T12 to T1.
  • This then transitions to a trend toward a more lateral and caudal pedicle starting point as one proceeds proximally from the apex.

Lumbar Spine Anatomy
• The lumbar vertebral facets are more sagittally oriented in comparison to thoracic vertebral facets.
• Pedicles
  • Dimensions
    • In scoliotic spines, average lumbar pedicle length is 20 to 22 mm.
    • Average lumbar cord length is 45 to 48 mm.
  • Coronal anatomy
    • Average lumbar endosteal pedicle width is 4.8 to 9.5 mm.
    • The larger size of the lumbar pedicles increases the likelihood of optimal placement of pedicle screws.
  • Transverse orientation
    • L1 pedicles are perpendicular to the floor in the transverse plane.
    • L5 pedicles subtend an angle of about 25 to 30 degrees with the midline in the transverse plane.
    • Lumbar pedicles progressively angle outward in the transverse plane, proceeding inferiorly from L1 to L5.
  • Lumbar pedicle screw starting points
    • The long axis of the pedicle pierces the lamina at the intersection of two lines: a vertical line tangential to the lateral border of the superior articular process, and a horizontal line bisecting the transverse process (FIG 3).
    • The point of intersection for these two lines lies in the angle between the superior articular process and the base of the transverse process.
• Dangers
  • Medial pedicular breaches endanger the dural sac, especially on the concavity of the curve.
  • Inferior pedicular breaches endanger the nerve root, especially in the lumbar spine.
  • Advancement of pedicle screws following a lateral pedicular breach on the left can endanger the lung, segmental vessels, and sympathetic chain (T4–T12) and the aorta (T5–T10).
Advancement of pedicle screws following a lateral pedicular breach on the right can endanger the lung, segmental vessels, sympathetic chain, and azygous vein (T5–T11). Advancement of pedicle screws following a breach of the anterior cortex on the right can endanger the superior intercostal vessels (T4–T5), the esophagus (T4–T9), the azygous vein (T5–T11), the inferior vena cava (T11–T12), and the thoracic duct (T4–T12). Advancement of pedicle screws following a breach of the anterior cortex on the left can endanger the esophagus (T4–T9) and the aorta (T5–T12).

**PATHOGENESIS, NATURAL HISTORY, AND PATIENT HISTORY AND PHYSICAL FINDINGS**

See Chapter PE-56, Posterior Exposure of the Thoracic and Lumbar Spine.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Placement of a pedicle screw at the thoracolumbar junction followed by intraoperative fluoroscopic imaging accurately identifies vertebral level.

With use of intraoperative fluoroscopic imaging guidance, knowledge of anatomy remains critical in order to orient the intensifier to obtain the best coronal images of the pedicles.

Radiographic criteria used to evaluate accurate screw placement

- Harmonious segmental change of the tips of the pedicle screws on the posteroanterior (PA) radiograph
- No crossing of the medial pedicle wall by the tip of the pedicle screw with reference to vertebral rotation on the PA radiograph
- No violation of the imaginary midline of the vertebral body by the tip of the pedicle screw on the PA radiograph
- No breach of the anterior cortex of the vertebral body on the lateral radiograph

**DIFFERENTIAL DIAGNOSIS**

- Scoliosis
- Idiopathic
- Congenital
- Neuromuscular
- Limb-length discrepancy
- Osteoid osteoma
- Sprengel deformity

**NONOPERATIVE MANAGEMENT**

- Observation for progression for curves of 0 to 20 degrees. Patients are followed with serial clinical and radiographic examinations.
- Bracing for progressive curves of 20 to 40 degrees if the patient is skeletally immature. Braces are unable to correct curves; their purpose is to prevent curve progression.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

- PA and lateral radiographic views of the entire spine.
- Convex apical pedicles greater than 5 mm in diameter on the PA radiographs are large enough to accommodate pedicle screw placement.
- Computed tomographic (CT) imaging can be used to evaluate pedicle morphology, with images oriented perpendicular to the plane of the vertebrae.
- Fusion levels are chosen based on the Lenke criteria.

**Hook Placement**

**Advantages**

- Technically easier, especially at levels with small pedicles (apical concave pedicles)
- Less operative time

**Disadvantages**

- Increased canal intrusion in comparison to pedicular fixation
- Lack of three-column fixation
- Decreased ability to perform correctional derotational maneuvers

**Types of hooks**

- Laminar hooks: should be used with caution in the neurologically intact patient
- Thoracic laminar hooks: downgoing sloped hooks
- Lumbar laminar hooks: upgoing or downgoing C-shaped hooks
- Thoracic transverse process hooks: downgoing C-shaped hooks
- Thoracic pedicle hooks: upgoing claw-tip hooks placed under the lamina
- Offset hooks: offset laterally to lie in line with pedicle screws for use in hybrid constructs
- Hook patterns for an isolated thoracic curve
- Concave side
  - Upgoing pedicle hook on upper end and upper intermediate vertebrae
- Downgoing laminar hook on lower end and lower intermediate vertebra
- Convex side
- Claw construct at upper end vertebrae.
- Downgoing transverse process hook with upgoing pedicle hook at the same level or next-distal level. Splitting the claw over two levels (split claw) better resists rotational forces.

### Pedicle Screw Placement

#### Advantages
- Pedicle screws have significantly higher axial pullout strengths than supralaminar hooks and pedicle hooks.
- Better correction in the coronal and axial planes.
- Less decrease in pulmonary function than anterior surgery.
- No implants in the canal during the correction phase.
- Correction not gained by pure distraction.
- Fewer fusion levels.
- No crankshaft.
- Larger area for bone graft.
- Allows earlier postoperative activity.

#### Disadvantages
- Steep learning curve.
- Caudal or medial penetration can result in dural or neural injury.
- Lateral penetration can cause vascular injury.
- Increased operative time.
- Costly procedures.

#### Complications
- Suboptimal screw position
  - More common in cases of severe deformity
  - Perforation not uncommon (up to 40% of screws in some series)
  - Lateral perforation more common than medial perforation
  - Lowest containment rates in midthoracic spine (T5 to T8)
- Dural, neural, or vascular injuries occur infrequently.

#### Types of pedicle screws
- Monoaxial
  - No motion between the screw and the screw head
  - Can obtain axial correction of deformity
- Uniaxial
  - Motion between the screw and the screw head constrained to one plane
  - Can accommodate sagittal contours while retaining ability to obtain axial correction (derotation)
- Polyaxial
  - Multiaxial motion allowed between screw and screw head
  - For accommodation of sagittal contours
  - Can accommodate malalignment of the starting points in the coronal plane
- Reduction screw
  - Pedicle screw with breakaway extended tabs
  - Useful for seating rod into pedicle screw for difficult reduction maneuvers
- Freehand placement of thoracic pedicle screws
  - The straightforward trajectory allows for fixed-head screws and true direct vertebral derotation.

- Anatomic trajectory has a longer bone channel and allows a longer screw to be placed, but mandates the use of a multiaxial screw to connect it to the rod.
- A straightforward trajectory paralleling the superior endplate has significantly higher pullout strength versus an anatomic trajectory that angles about 22 degrees in the cephalocaudal direction perpendicular to the superior facet.7
- Extrapedicular thoracic pedicle screws
  - Screw inserted at the junction of the cephalad tip of the transverse process and the rib with advancement caudal so that the screw is contained in the pedicle rib unit, defined as the space between the lateral pedicle cortex and medial rib cortex.
  - Similar biomechanical fixation strength of transpedicular screws.

#### Confirmation of screw placement
- Radiographic confirmation (see Imaging and Other Diagnostic Studies)
- Neuromonitoring
  - Electromyography to confirm intraosseous screw placement
  - Somatosensory evoked potentials and motor evoked potentials
- Postoperative CT scan routinely performed before patient leaves the hospital to confirm accurate screw placement

### Positioning

- Patient is intubated in the supine position on the stretcher.
- Neurologic monitoring leads are placed cranially, on the intercostal and abdominal musculature, and on all four extremities.
- Multiple large-bore intravenous access is obtained for fluid management and an arterial line is placed for intraoperative blood pressure monitoring.
- The patient is transferred to the prone position on a well-padded operating room table such as a Jackson frame (Orthopaedic Systems, Union City, CA).
- Care should be given to the degree of hip flexion–extension, as this can affect the amount of lordosis in the lumbar spine.
- Bolsters underneath the chest and anterior superior iliac spines prevent abdominal compression and allow epidural venous return, thus decreasing epidural bleeding.
- All bony prominences are well padded, including medial elbows, knees, pretibial areas, and ankles.
- Care is taken to avoid abduction and forward flexion past 90 degrees at the shoulder and flexion past 90 degrees at the elbow.
- Skin is shaved if excessively hairy.
- Clear adhesive surgical drapes (3M Steri-Drape Towel Drapes) are placed around the perimeter of the surgical site, extending from the hairline to the top of the gluteal crease (regardless of levels to be fused, the entire spine should be draped).
- If a wake-up test is going to be used by the surgical team, a clear plastic C-arm cover or equivalent clear drape is laid over the exposed feet for visualization during the test.
- A disposable plastic ruler used for measuring the pedicle probe for pedicle depth is placed caudal to the field on the buttocks and covered with a clear Tegaderm dressing.
HOOK PLACEMENT

Proper hook-site preparation is critical to obtain a stable construct and minimize the chance of hardware failure.

Ideally, hooks should be placed flush with the bony surfaces to evenly distribute forces and minimize the chance of hook pullout. This is accomplished by meticulous removal of the soft tissues and judicious contouring of the bony surfaces: removing too much bone can weaken hook purchase, whereas removing too little bone can result in improper seating of the hook.

Pedicle Hooks

Initial pedicle hook-site preparation requires removal of a small portion of the inferior facet with an osteotome (TECH FIG 1A,B). The inferior facet of the superior vertebra is osteotomized using an osteotome. A vertical cut is made at the medial edge of the facet, near the base of the spinous process. A horizontal cut in the inferior facet, allowing removal of 3 to 4 mm of bone, follows for insertion of the pedicle hook.

The exposed hyaline cartilage from the facet joint is removed. A pedicle finder is introduced into the facet joint and gently impacted into place with a mallet (TECH FIG 1C,D). Care is taken to avoid canal penetration.

The permanent pedicle hook is subsequently inserted (TECH FIG 1E,F). The surgeon must carefully visualize the facet joint and avoid inserting the pedicle hook into the laminae. If the lamina is split by the hook, fixation will be compromised.

Laminar Hooks

Laminar hooks are placed in a similar fashion but require great care because they are positioned in the spinal canal (TECH FIG 2A,B).

To obtain entrance into the canal, the ligamentum flavum is carefully dissected from the laminae and completely removed with curettes and rongeurs until the dura can be visualized. Small laminotomies are performed to allow room for hook insertion (TECH FIG 2C,D).

A hook starter is then used to create a path for the hook (TECH FIG 2E). The hook is then placed into the path created (TECH FIG 2F).

Transverse Process Hooks

Transverse process hooks do not require extensive bone removal but may require minimal contouring to optimize fit (TECH FIG 3A,B).

The costotransverse ligaments on the superior side of the transverse process are divided with a periosteal elevator. The transverse process hook is seated around the transverse process (TECH FIG 3C,D).

TECH FIG 1 • Placement of pedicle hook. A,B. A small portion of the inferior facet is osteotomized. C,D. Introduction of pedicle finder into facet joint, taking care to avoid canal penetration. E,F. Insertion of pedicle hook.
TECH FIG 2 • Placement of supralaminar hook. A,B. Placement of a supralaminar hook is difficult without bone removal to allow room for hook insertion. C,D. Placement of supralaminar hook. Laminotomies allow room for hook insertion. E. Path for hook created with hook starter. F. Insertion of supralaminar hook.

TECH FIG 3 • A,B. Placement of transverse process hook. Contouring of the transverse process is required to optimize fit. C,D. Placement of transverse process hook. After contouring the transverse process, the transverse process hook is seated.
EXPOSURE FOR THORACIC PEDICLE SCREW PLACEMENT

- Full exposure of the facet joint, the pars interarticularis, and the entire transverse process aids in identification of the ideal starting point.
- Once the entire spine is exposed, each level is considered independently. The surgeon needs to visualize the local topical anatomy and the effects of the scoliosis on the anatomy (rotation).
- Bovie cautery is used to outline the osseous anatomy at each level. This first entails finding the medial and lateral border of the facet and the superior and inferior borders of the transverse process (TECH FIG 4A).
- The inferior facet of the superior vertebrae is osteotomized using an osteotome at the medial edge of the facet (TECH FIG 4B) and at the inferior border of the superior transverse process (TECH FIG 4C).
- At this point, the facet joint should be fully exposed (TECH FIG 4D), thus facilitating identification of the starting point.

![TECH FIG 4 A. The medial and lateral borders of the facet joint are identified. B. The inferior facet of the superior vertebrae is osteotomized at its medial edge. C. The facet is osteotomized at the inferior border of the superior transverse process. D. Full exposure of the facet joint facilitates identification of the starting point.]

THORACIC PEDICLE SCREW PLACEMENT

- A 3.5-mm acorn-tipped burr is then used to create a hole at the desired starting point (see Thoracic Anatomy) (TECH FIG 5A). A cancellous blush often heralds entry into the pedicle but can be a false positive found on entry into the transverse process.
- A specialized thoracic probe with a 2-mm blunt tip and a 35-mm curved segment with a rectangular cross section (Lenke probe) is used to create the tract for the pedicle screw.
- The probe is introduced into the starting point with the curvature oriented so the tip is pointed laterally to avoid medial pedicle cortical violation (TECH FIG 5B).
- The cancellous soft spot signifies entry into the pedicle.
- The probe is advanced using ventral pressure and axial rotation to a depth of about 15 to 20 mm (the length of the pedicle), using the appropriate orientation for the particular vertebral level (see Thoracic Pedicle Anatomy) and taking care to account for the scoliotic deformity.
- The probe is then removed and reintroduced into the previously developed tract with the tip turned medial to avoid lateral vertebral body cortical violation (TECH FIG 5C).
- The probe is advanced to a depth appropriate for the particular vertebral level, taking care to avoid anterior and lateral cortical violation.
- Typical cord lengths (distance from posterior cortical starting point to anterior vertebral cortex in line with the axis of the pedicle):
  - Lower thoracic 40 to 45 mm
  - Midthoracic 35 to 40 mm
  - Upper thoracic 30 to 35 mm
- The tract is probed using a flexible sound and five distinct bony borders are palpated: superior, inferior, medial, and lateral walls and the floor.
- The first 15 to 20 mm of the tract corresponds to the pedicle; its integrity should be critically assessed.
- The depth is measured with the flexible sound in the base of the tract using a hemostat (TECH FIG 5D).
The tract is tapped (TECH FIG 5E). Undertapping by 1.0 mm creates a 93% increase in maximal screw insertion torque.\textsuperscript{5}

The tract is again probed for a breach with the aid of the feel of the tapped threads.

Screw diameter is based on radiographic evaluation of pedicles.

The screw is placed slowly to allow for viscoelastic expansion of the pedicle (TECH FIG 5F).

LUMBAR PEDICLE SCREW PLACEMENT

- Full exposure of the facet joint, the pars interarticularis, and a portion of the transverse process aids in identification of the ideal starting point.
- The facet joint is removed to obtain a flat surface before placing the pedicle screw.
- A 3.5-mm acorn-tipped burr is then used to create a cortical breach at the desired starting point.
- A specialized probe with a blunt spatula tip and a 35-mm curved segment with a rectangular cross section (lumbar probe) is used to create the tract for the pedicle screw.
- The tract is tapped. Undertapping by 1.0 mm creates a 93% increase in maximal screw insertion torque.\textsuperscript{5}
- The tract is again probed for a breach with the aid of the feel of the tapped threads.
- Screw diameter is based on radiographic evaluation of pedicles.
- The screw is placed slowly to allow for viscoelastic expansion of the pedicle.

TECH FIG 5 • A. A burr is placed at the correct starting point. B. After the cortex is breached, a curved probe is placed into the pedicle with the tip pointing laterally to minimize risk of medial pedicle breach and potential cord injury. C. After probing past the pedicle, its tip is then turned to point medially to minimize risk of vertebral body cortical breach. D. After probing the tract, the depth is measured. E. The tract is tapped. F. The pedicle screw is inserted.

POSTOPERATIVE CARE

- No postoperative immobilization is required with multisegmental constructs.
- Postoperative restrictions include limitations with lifting, bending, and twisting.
- It is important to maintain mean arterial blood pressure above 70 mm Hg overnight and hemoglobin above 10 g/dL to maintain spinal cord perfusion.
- Intravenous antibiotics are maintained for 48 hours postoperatively.
- Neurovascular checks are made every 2 hours for the first 8 hours and then every 8 hours.
- Patients are out of bed on postoperative day 1.
- Foley catheter is removed on postoperative day 2.
- Diet is advanced as tolerated.
- Patient-controlled analgesia is used for appropriate patients.

OUTCOMES

- With meticulous attention to detail with regard to instrumentation and fusion techniques, excellent outcomes in terms of straightening and fusion of the scoliotic spine can be expected.
- Long-term outcomes are variable and depend on the underlying diagnosis and the extent of retained spinal mobility.

COMPLICATIONS

- Wrong-level surgery
- Failure of fusion
- Hardware malfunction
- Neurologic injury
- Dural tear
- Pneumothorax
- Crankshaft
- Superior mesenteric artery syndrome
- Loss of lumbar lordosis

REFERENCES

DEFINITION
- Kyphosis in the patient with myelomeningocele can occur at the thoracolumbar junction, the midlumbar spine, or the lumbosacral junction.
- The different types of kyphosis have some bearing on the treatment needed for the repair, but whether the origin is congenital, developmental, or paralytic, the consequences can be devastating for the child with this condition.
- Skin breakdown over the apex of the kyphosis can develop deep wound infections and lead to central nervous system infections.
- Secondary changes in other organ systems can create compromise in the gastrointestinal or genitourinary systems or even potentially disastrous kinking of the great vessels due to compromise in the abdominal height. Diminished absorption frequently occurs in the gastrointestinal tract, and renal calculi may develop from poor urinary drainage.
- Secondary effects on the pulmonary capacity produce thoracic insufficiency syndrome because the abdominal contents are pushed into the thoracic cage. Added to this is a secondary thoracic lordosis cephalad to the kyphosis.
- Bracing generally leads to problems from skin pressure and ultimately does not solve the problem.

ANATOMY
- The kyphotic angle can be gradual or acute.
- The paraspinal musculature is partially innervated in a flexion position lateral to the bony ridges owing to lack of posterior migration from an embryologic origin. In this position, they contribute to forward flexion of the spinal column.
- The bony ridges laterally in the area of the diastasis leave little bone for fusion mass on the posterior side of the vertebral column.
- The midline defect from the original myelomeningocele characteristically is covered by a fragile dura separated from the overlying skin by a thin layer of subcutaneous tissue.
- The soft tissue coverage is made worse by poor nutrition.
- One of the most reliably formed vertebral structures is the sacral ala.
- The great vessels generally do not follow the kyphotic contours into the kyphotic apex.

PATHOGENESIS
- Embryologically the notochord is covered dorsally by closure of the ectoderm over top of it, progressing in a cephalic to a caudal direction. In myelomeningocele, the closure is incomplete, usually at the caudal end.
- Less common types of myelomeningocele occur in the thoracic and cervical area. Thoracolumbar, lumbar, and lumbosacral kyphosis is the most commonly seen type and occurs because of lack of posterior migration of the ectoderm surrounding the notochord, leaving the neural placode in a vulnerable position, exposed at birth.
- Congenital bony defects occurring in this area lead to an early-onset kyphosis that can pose significant problems for the neurosurgeon’s closure at birth. This has led some experts to encourage neonatal correction of the kyphosis.
- With further growth and an upright sitting posture, the paraspinal musculature, which has formed in a lateral and anterior position, pulls the upper torso into a more kyphotic position, both actively through muscle contracture and secondarily from gravity.
- This can lead to further skin compromise and pressure in the soft tissues overlying the kyphosis.
- Skin breakdown can be a serious problem over the kyphosis.
- The C7 lateral plumb line shows the upper torso to be far out of balance in a forward-flexed posture, leading to thoracic insufficiency from the abdominal contents pressing under the diaphragm.
- This can render the child a “functional quadriplegic” since he or she uses the upper extremities for balance and to unweight the diaphragm by pivoting on the extended arms for breathing purposes (marionette maneuver; FIG 1).
- From a developmental standpoint, this can further limit the young child’s upper extremity interaction with his or her environment, which is essential for the development of normal intelligence.

NATURAL HISTORY
- The natural history of unpublished cases of severe kyphosis is one of thoracic compromise from insufficiency syndrome, progressive decline in pulmonary capacity, and death.

FIG 1 • “Functional quadriplegia” in myelokyphosis; lumbar kyphosis with thoracic lordosis.
PATIENT HISTORY AND PHYSICAL FINDINGS
- A careful history and physical examination should elicit possible signs and symptoms of associated anomalies, including:
  - Chiari malformation
  - Tethered cord
  - Respiratory compromise
  - Gastrointestinal malabsorption
  - Urinary hydrostasis and lithiasis
- Physical examination of the child should include flexibility tests of the curve by physically supporting the child under the armpits to suspend him or her against gravity. Bending back supine on the examining table can also indicate the extent of lumbar flexibility.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standard radiographs, anteroposterior (AP) and lateral views of the full spine, in the upright sitting posture assess the effects of gravity upon the curve (FIG 2A,B).
- Supine radiographs are helpful for visualization of bony definition.
- Flexibility films with traction, manual push, or back bending over a bolster with a shoot-through lateral film, are helpful adjuncts.
- CT scans, especially three-dimensional CT scans, offer the best delineation of the anatomy.
- MRI is critical for assessment of the intrathecal structures and assessing for Chiari malformation, syringomyelia, and tethering (FIG 2C).

DIFFERENTIAL DIAGNOSIS
- Congenital versus developmental kyphosis
- Sacral agenesis
- Charcot joints secondary to vertebral column breakdown across the apex of the kyphosis

NONOPERATIVE MANAGEMENT
- Bracing has no place in the treatment of this disorder.
- Occasionally traction is helpful to stretch the kyphosis, especially in a developmental type to aid in correction at the time of surgery.
- This can be done with cervical traction or halo traction, and some authors have promoted the use of this traction during the time of surgery to aid in the correction.

SURGICAL MANAGEMENT
Preoperative Planning
- Vascular monitoring devices are an important adjunct during surgery, and either arterial lines or pulse oximeters on both feet are important to monitor blood supply to the lower extremities at the time of correction.
- A great deal of tension can be placed on the aorta at the time of kyphosis realignment. Thus, arterial and central venous lines are necessary to monitor central pressure and allow for rapid medication administration.
- Areas of skin breakdown should be addressed and healed prior to kyphectomy.
- Preoperative planning may include assessment by a plastic surgeon and possible need for placement of tissue expanders in the posterolateral axillary margins to aid in skin closure at surgery (FIG 3).
- As a part of the preoperative planning, all imaging studies are carefully reviewed to assess flexibility, the adequacy of the vertebral bodies to tolerate pedicle screws, and planning for which levels will need to be decancellized or removed.
- It is recommended that these plans be recorded on a “blueprint” that can be placed on the operating room wall outlining the location of implants, osteotomies, and order of progression for the surgical plan.
- Assessment by neurosurgery is necessary preoperatively regarding shunt functioning and review of the MRIs.
- Preoperative antibiotics are essential, including gram-negative coverage for urinary pathogens. These are continued postoperatively for 6 to 12 weeks.

FIG 2 • A,B. A 13-year-old with myelokhyphosis with diastasis beginning at T6 with 127 degrees of kyphosis. C. Preoperative MRI in a 9-year-old with myelomeningocele before undergoing kyphectomy with growing construct.

FIG 3 • Myelomeningocele in an 11-month-old with tissue expanders placed bilaterally before delayed closure and kyphectomy.
Nutritional status is maximized and may require hyperalimentation via a gastrostomy tube button months ahead of surgery to maximize postoperative healing.

**Positioning**

- During positioning, careful padding with extra foam is essential to protect delicate skin during a prolonged operation.
- Eye protection to guard against intraoperative ocular compromise and a spinal frame that allows for suspension of the abdominal structures will diminish the epidural vascular pressure.
- Preoperative assessment of the hips is important to anticipate the intraoperative positioning, and if the flexion contractures about the hips are too severe, a preliminary release of contractures done a few weeks ahead of time may be necessary to allow for proper positioning of the legs at the time of the kyphectomy.

**Approach**

- The surgical incision may involve excision of compromised skin lesions or scars, although this is best addressed before surgery.
- The previous incisions on a myelomeningocele back may not be midline or ideally placed.
- The best skin incision for kyphectomy should follow the previous skin incisions to maximize blood supply to the skin edges at closure. Maximum skin and subcutaneous tissue coverage is important for good skin closure.
- If a compromise in the quality of soft tissues is anticipated, then previously placed tissue expanders may be removed from the midline at closure and the expanded tissue brought to the midline.
- There may be times when the poorly healed, convoluted scars from previous neurosurgical interventions may be harbingers of bacteria that will not promote adequate healing or may contribute toward postoperative infection. Preliminary excision of the scars by plastic surgery may afford the best defense against outside-in infections.

**INCISION AND LUMBAR DISSECTION**

- The incision—either straight or curvilinear—follows the previous scars. It is extended deep to the spinous processes in those sections where they exist.
  - The caudal portion of the incision is made to the level of the dura, with care taken to avoid laceration of the fragile dura.
- The surgical plane is then deviated to the right and left side superficial to the dura while palpating for the lateral bony elements. The deep portion of the incision is directed toward the bone.
  - It is desirable to maintain as much subcutaneous thickness as possible.
  - If there are lacerations of the dura, it is best to stop and sew them as one proceeds since the thinned dura may require a flap of adjacent tissue for a watertight closure. Sometimes it is necessary to sew in a piece of Duragen sealant to ensure a watertight closure.
  - Four-O Neurolon on a small needle in a running fashion works quite well for an incidental durotomy repair.
- As one proceeds from distal to proximal in the lumbar spine, the lateral elements are palpated and with the use of electrocautery, the soft tissues are incised to bone.
- The muscle and soft tissue attachments to the laterally positioned lumbar bones are released to reveal the underlying bony elements that embryologically would have progressed posteriorly to become the lamina and facets (TECH FIG 1A–C).

**TECH FIG 1** • **A.** Intraoperative dissection with neuroplacode left in place and forceps placed on bilateral bony ridges. **B.** Paraspinal muscles are dissected away from the kyphosis, with frequent irrigation of neural elements. **C.** In a different patient, the kyphosis has been dissected out. **D.** The neuroplacode can be left in place, mobilized to one side by releasing nonfunctioning nerve roots over four levels, or resecting to the level of the diastasis and oversewing.
Chapter 58  
KYPHECTOMY IN SPINA BIFIDA

TECHNIQUES

THORACIC DISSECTION

- Once the lumbar spine is dissected, the thoracic area is approached.
- If one is contemplating a fusion of the thoracic spine, such as in a child over 8 years of age, full dissection out to the tips of the transverse processes should be accomplished.
- If a growing rod construct is being used, such as in a child under age 8 years, this is done with minimal dissection so as to promote growth.
- If the growing construct is desired, the muscle and soft tissue attachments are cleaned from the sides of the spinous processes as far as the facet joints.
- One needs to be able to visualize the ligamentum flavum sufficiently to pass sublaminar wires for the Luque trolley portion of the “growing” construct.
- Generally, four thoracic levels for wires are all that is necessary.
- In the lumbar spine, soft tissues should be cleaned from bone sufficiently to allow for fusion between the lateral elements and to the sacrum.
- At this point in the operation, radiographic C-arm guidance is helpful for placement of pedicle screws.
- The entrance point for the lumbar dysplastic pedicles is in a lateral position, with the pedicles directed obliquely toward the vertebral body (TECH FIG 2).
- Bilateral screws can be obliquely placed for fixation.
- Fixation to the pelvis can be done with multiple types of fixation devices, including S-rods, S-hooks, and iliac threaded bolts.
- Fusion to the sacrum is essential to firmly plant the rod on the pelvis and allow for growth off the top of the rods in the thoracic spine.
- The C-arm is used in both AP and lateral positions to confirm satisfactory placement of the screws in bone. Bicortical fixation is generally not necessary because of the strong fixation supplied by the triangulation of the screws.
- Polyaxial screws are desirable through the lumbar segments.

PEDICLE SCREW PLACEMENT

- The rudiments of these bones can be visualized along with a transverse process at each level in the bony ridge of the diastasis.
- The medial neural placode is left intact since it acts as third-space filler and padding for the implants.
- There may be instances in which the neuroplacode has to be mobilized, and this is done by releasing nonfunctioning roots on one side and reflecting the dura laterally to gain access to the disc space and underlying vertebrae (TECH FIG 1D).
- One needs to be able to visualize the ligamentum flavum sufficiently to pass sublaminar wires for the Luque trolley portion of the “growing” construct.
- Generally, four thoracic levels for wires are all that is necessary.
- In the lumbar spine, soft tissues should be cleaned from bone sufficiently to allow for fusion between the lateral elements and to the sacrum.

DECANCELLIZATION

- Decancellation can be accomplished at multiple levels, leaving adequate vertebral levels for fixation and correction. Ideally, it is accomplished at one or two levels in a location that will leave sufficient midlumbar fixation points to push the vertebrae forward to create lordosis.
- The levels chosen for decancellation are approached after screw placement, based on the preoperative planning.
- The decancellation begins with a burr at the entrance to the pedicle. It continues with enlarging sizes of curettes, saving the bone for the fusion.
- The inside of the vertebral body is completely cored out, and when bleeding points are encountered, the pedicle can be filled with FloSeal and if necessary further packed with some rolled Gelfoam to stop the bleeding.
- Care is taken to avoid violating the posterior cortex of the vertebral body until the very end, since this is where the epidural vessels are most prolific.
- The lateral margins of these vertebral bodies are removed, including the transverse process and posterolateral bone.
- The decancellation should be thorough, leaving only the cortex. This is carried out bilaterally followed by implosion of the posterior cortex with an Epstein curette, pushing the bone fragments into the cavity of the vertebral body (TECH FIG 3).
- Bleeding points are stabilized.
- In most instances, decancellation alone at select levels is all that is necessary to gain the mobility for correction.
Occasionally, removal of a vertebral segment may be indicated. If so, it can be accomplished while maintaining the neuroplacode.

The vertebral section for removal in that instance would be taken from that section of the curve that is horizontal and cephalad to the apex of the kyphosis (TECH FIG 4).

TECH FIG 4 • A. If bone is to be resected (due to extreme stiffness), this should be done in the horizontal section at the top of the kyphosis, not at the apex. B. After horizontal resection, the bone is pushed forward to realign. C. After resection, realignment and fixation are accomplished.

ROD PLACEMENT

Once these corrective maneuvers have been completed, rods linked to the sacrum can then be placed bilaterally to push the vertebral bodies anteriorly into a straight or preferably a lordotic position (TECH FIG 5A).

Through gradual approximation of the rod forward toward the thoracic fixation points, the lumbar segments are brought into alignment and the rods gradually tightened to the wires of the thoracic spine (TECH FIG 5B,C).

TECH FIG 5 • A. Bilateral rods are anchored to L4 and S-hooks in preparation for reduction. B. Decancellized levels are crushed by compressing adjacent screw heads. C. In a different patient, gradual reduction with wires and provisional tightening are accomplished using a growing construct. (continued)
Physiologic kyphosis can be contoured into the thoracic component of the rods to correct the thoracic lordosis.

- Generally, the rods are left one level long at the top to allow for growth in the thoracic spine.
- The final tightening should produce some distraction between the lowest lumbar segment fixation point and the S-hooks pushed against the sacral ala (TECH FIG 5D, E). This will set the S-hooks in place securely.
- Final contouring with the in situ benders can allow for further lordosis of the lumbar spine if desired.

ASSESSING AND MANAGING LOWER EXTREMITY HYPOPERFUSION

- Frequently, the initial maneuvers for correction across the kyphosis are accompanied by a decrease in blood flow to the lower extremities. Therefore, it is important to do this corrective maneuver gradually in small increments.
- The baroreceptors in the aorta can accommodate to the change in alignment and stretch. If the blood flow to the feet is unable to accommodate to the new position of the spine, further decancellation or vertebral body removal will be necessary.
- This decision is based on the flow to the lower extremities reflected in the pulse oximeter or arterial catheters in the feet.

CLOSURE

- As part of the closure, it is important to grasp the paraspinal musculature with clamps to pull the muscles toward the midline by elevating and mobilizing the muscle layer with a Cobb elevator.
- Sometimes release of the fascia on the posterior side of the musculature is necessary, and this is best done in the posterior axillary line with a vertical cut in the fascia.
- The paraspinal musculature should be brought as close as possible toward the midline on both sides and sewn down (TECH FIG 6).
- At least one and more likely two Hemovac drains should be left, one in the deep and one in the superficial layers, for drainage over 1 week to 10 days postoperatively.
- Subcuticular closures can be used, but they should be reinforced with external suture of some kind, either clips or interrupted nylon sutures on a temporary basis.

TECH FIG 5 • (continued) D. Completed reduction in patient in A and B. Allograft and autograft have been applied to decorticated bone for fusion. E. Completed reduction in patient with growing construct in C.

TECH FIG 6 • The paraspinal muscle flaps are brought to midline for final closure.
### Pearls and Pitfalls

<table>
<thead>
<tr>
<th>Evaluation</th>
<th>The surgeon can assess flexibility of the curve by physically supporting the child under the armpits to suspend him or her against gravity. Bending back supine on the examining table can also indicate the extent of lumbar flexibility.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Preoperative preparation</td>
<td>Areas of skin breakdown should be addressed and healed before kyphectomy.</td>
</tr>
<tr>
<td>Intraoperative monitoring</td>
<td>Vascular monitoring of the lower extremities is a critical part of the intraoperative monitoring.</td>
</tr>
<tr>
<td>Preoperative preparation</td>
<td>Preoperative antibiotics are essential, including gram-negative coverage for urinary pathogens. These are continued postoperatively for 6 to 12 weeks.</td>
</tr>
<tr>
<td>Managing incidental durotomy</td>
<td>Four-O Neurolon on a small taper needle in a running fashion works quite well for an incidental durotomy repair. Duragen can be sewn over the repair, and occasionally the use of a sealant (Tusseal) is necessary.</td>
</tr>
<tr>
<td>Preventing epidural bleeding</td>
<td>Care is taken to avoid violating the posterior cortex of the vertebral body until the very end, since this is where the epidural vessels are most prolific.</td>
</tr>
<tr>
<td>Setting the S-hook</td>
<td>The final tightening should produce some distraction between the lowest lumbar segment fixation point and the S-hooks pushed against the sacral ala. This will set the S-hooks in place securely.</td>
</tr>
<tr>
<td>Postoperative care</td>
<td>All reasonable measures must be taken to avoid any pressure on the wound or extremities in the postoperative period. All areas of insensate skin must be protected from excessive pressure with frequent change in position on a soft surface. The dressings should be covered with a waterproof covering to protect against secondary contamination from stool.</td>
</tr>
</tbody>
</table>

### Postoperative Care
- For recovery, patients are placed on their back with an extra-thick foam on top of the mattress to avoid excessive skin pressure.
- Logrolling is instituted 6 hours postoperatively and repeated every 2 hours.
- Recovery occurs in the intensive care unit until the patient is sufficiently stable.
- Although postoperative immobilization is not necessary, if desired it can be accomplished with careful molding of a bi-valved jacket with a Plastizote soft lining.

### Outcomes
- Improved sitting
- Improved respiratory function
- Better blood supply to skin

### Complications
- Skin breakdown
- Infection, superficial or deep
- Vascular compromise to feet with stretch on aorta
- Loosening of spinal implants
- Pseudarthrosis

### Reference
DEFINITION
- Thoracic scoliosis and thoracolumbar–lumbar scoliosis are typically curves seen in idiopathic scoliosis and can be treated anteriorly.
- Anterior arthrodesis refers to the fusion of the anterior part of the vertebral bodies, usually with instrumentation for these curve patterns.

ANATOMY
- Thoracic idiopathic scoliosis usually has an apex at T8 or T9. It is the most common right convex curve pattern and has axial-plane rotational deformity as well as hypokyphosis.
- The vertebral bodies are nearly normal in their shape, although some distortion of the vertebral body and pedicles is seen, with thin long pedicles on the concavity and shorter, wider pedicles on the convexity.
- Thoracolumbar–lumbar scoliosis has an apex of the curve at T12 or below and is most commonly a left-sided curve, with or without a compensatory thoracic curve.

PATHOGENESIS
- The cause of idiopathic scoliosis is not yet known.

NATURAL HISTORY
- Idiopathic scoliosis progresses with continued growth of the spine, especially during the peak growth periods and when the curve magnitudes are “large” at the completion of growth.
- Thoracic curves tend to progress at skeletal maturity when the curve is greater than 45 to 50 degrees.
- Thoracolumbar–lumbar curves tend to progress when the curve is greater than 35 to 40 degrees at the time of skeletal maturity.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients with thoracic scoliosis and thoracolumbar scoliosis should be evaluated for their perception of spine and body deformity to include asymmetric shoulder elevation, trunk shift, waistline asymmetry, and rib or flank prominence.
- Pain in the axial spine and pain radiating into the lower extremities should be ascertained with a good history; such symptoms warrant an MRI.
- Neurologic symptoms such as paresthesias, hyperesthesia, or bowel or bladder symptoms are relevant and require further imaging with an MRI.
- Physical examination should assess the trunk imbalance in the coronal plane, which can be seen with isolated thoracic or thoracolumbar–lumbar curves.
- The Adams forward bend test characterizes the axial-plane deformity seen in scoliosis and is used to assess rotational deformity of the thoracic rib prominence or the flank prominence. The rotational deformity of the thoracic and lumbar spine is graded using a scoliometer with the patient bending forward. The rotational deformity seen in scoliosis can be very prominent and the most obvious deformity seen by patient and families.
- Cutaneous manifestations of dysraphism should also be analyzed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) and lateral radiographs of the spine should be obtained to review the coronal and sagittal plane deformities, respectively (FIG 1).
- On the AP radiograph, the coronal plane deformity is measured using the Cobb method. Truncal imbalance can be measured using the Floman method (bisecting the distance between the lateral rib margins and comparing this point to the center sacral vertical line [CSVL]).
- The decompensation of the head relative to the pelvis is measured by the distance between the C7 plumb line and the CSVL.
- The Risser sign should be evaluated by assessing the ossification of the iliac apophysis, giving it a grade between 0 and 5.
- The triradiate cartilage status should be assessed as either open or closed.
- The lateral radiograph is used to measure thoracic kyphosis (measured from T3 to T12) and lumbar lordosis (from L1 to S1) as well as the sagittal balance (comparing a C7 plumb bob line to the front edge of S1).
- Supine best-bend radiographs can be used to determine the flexibility of the spine and are especially useful to determine the appropriateness of the surgical procedure.
whether the thoracolumbar–lumbar curve is flexible when a 
primary thoracic curve is present or if the thoracic curve is 
flexible and compensatory when the primary thoracolumbar–
lumbar curve is present.

DIFFERENTIAL DIAGNOSIS

- Idiopathic scoliosis should be differentiated from other 
types of scoliosis in which congenital abnormalities are not 
seen in ambulatory patients. This list includes neurofibromato-
sis, Marfan syndrome, type 3 spinal muscular atrophy, scolio-
sis associated with syringomyelia, or tethered cord.

NONOPERATIVE MANAGEMENT

- Adolescent thoracic and thoracolumbar scoliosis can be 
treated with bracing when curve magnitudes are between 25 
and 45 degrees during peak growth periods.
- Bracing is used for these curve magnitudes to prevent 
curve progression and is indicated in Risser grade 0 to 
2 patients.
- Nonoperative management is primarily indicated when 
the cosmetic appearance of the patient is acceptable to him 
or her.

SURGICAL MANAGEMENT

- Surgical indications for thoracic idiopathic scoliosis are 
curves exceeding 45 to 50 degrees with unacceptable cosmetic 
deformity.
- Indications for surgical treatment of thoracolumbar–lumbar 
curves are curves exceeding 40 to 45 degrees with unaccept-
able cosmetic deformity.

Preoperative Planning

- A careful physical examination as noted above is necessary 
to ensure that there are no neurologic signs or symptoms,
which would indicate neural axis abnormalities. If these are 
present, MRI of the neural axis is indicated.
- Radiographic imaging should be used to ensure the curve is 
characteristic of an idiopathic curve. For thoracic curve mag-
nitudes, this should demonstrate apical lordosis. The atypical 
curves, such as left-sided thoracic curves or those with signifi-
cant decompensation despite minimal rotational deformity, or 
patients who have excessive thoracic kyphosis should be fur-
ther evaluated with an MRI.
- The AP radiograph, the lateral standing radiograph, and the 
supine best-bend radiograph should be used to determine the 
Lenke classification.
- Specific detailed analysis of the compensatory curves should 
be performed to fine-tune a surgical plan to ensure that post-
operative decompensation does not occur. This is especially 
important to determine the flexibility of the lumbar curve and 
the lumbar modifier for primary thoracic curves, as well as the 
flexibility of the compensatory thoracic curve for primary tho-
racolumbar–lumbar curves.
- Anterior fusion levels for thoracic scoliosis are, in general, 
proximal-end vertebra to distal-end vertebra. Occasionally a 
parallel disc is noted at the distal segment. It is controversial 
whether this disc should be included in the fusion levels. When 
the curve is relatively small (50 to 60 degrees) and flexible 
greater than 50% flexibility index) and the patient is skele-
tally mature (triradiate cartilage is closed and Risser grade 1 or 
higher), inclusion of the parallel disc is not often necessary 
(Fig 2A,B).
- Anterior fusion levels for thoracolumbar–lumbar curves in 
general are proximal-end vertebra to distal-end vertebra. When the disc below the planned lowest instrumented vertebra 
is reversing and opening into the fractional lumbosacral curve, 
then disc wedging is not seen postoperatively. However, a disc 
below the lowest instrumented vertebra that is parallel preop-
eratively will often be wedged postoperatively (Fig 2C,D).

![Preoperative radiograph of a 13-year-old girl with a right thoracic curve measuring 52 degrees from T6 to T12. The disc at T11–12 is open into the right thoracic curve while the disc at T12-L1 is parallel.](A)

![A left thoracolumbar curve measured between T11 and L2 with a trunk shift to the left.](C)

![Two-year postoperative radiographs following an open anterior fusion and instrumentation from T11 to L2 with dual rod-dual screw system and anterior cages placed at the T12-L1 and L1-L2 levels with excellent coronal plane correction.](D)
Positioning

- Positioning for anterior surgery for either the thoracic or thoracolumbar curves is fairly similar.
- Patients are placed in the lateral decubitus position with the convex side of the curve up.
- An axillary roll is used for safe upper extremity neurologic function (FIG 3).
- An inflatable bean bag is used to position the patient, and body positioners can be added for further patient stabilization.
- For thoracolumbar–lumbar curves, a table that can be flexed allows for greater access to the abdomen and spine. It should be centered over the apex of the curve.
- For thoracic scoliosis surgery, the patient can be placed on a flat radiolucent table.

Approach

- The anterior approach is used for thoracic scoliosis.

OPEN THORACIC ANTERIOR INSTRUMENTATION AND ARTHRODESIS

- A curved incision is made over the proximal rib corresponding to the proximal fusion level (ie, commonly T5 with the fifth rib). The incision is carried through the thoracic and abdominal musculature to the periosteum of the rib.
- Subperiosteal dissection of the rib is performed circumferentially, and the rib is cut posteriorly and anteriorly.
- The parietal pleura is incised in a longitudinal fashion over the vertebral bodies across the intended levels of instrumentation and fusion.
- The segmental vessels can be temporarily ligated and spinal cord monitoring should be observed during temporary ligation.
- Permanent ligation can be performed after 20 minutes of normal spinal cord monitoring.
- Discectomy is performed (see below in the section on the thoracoscopic technique).
- Instrumentation is placed (see below).
- For the remaining procedures, see details under the thoracoscopic approach.

THORACOSCOPIC ANTERIOR INSTRUMENTATION AND ARTHRODESIS

Positioning, Preparation, and Draping

- After true lateral positioning is confirmed, fluoroscopy is used to mark the skin for the proximal-end vertebra and distal-end vertebra on the AP view. The skin markings are made to identify the angle of the proximal-end vertebra on the AP view (TECH FIG 1).
- The anterior and posterior edges of the vertebral bodies are then marked using the lateral fluoroscopy view.
- The chest and flank are prepared and draped in the normal sterile fashion.

Thoracoscopic Portal and Guidewire Placement

- An anterior portal is placed, bisecting the distance between the proximal and the distal intended instrumented vertebra, in the anterior axillary line. This portal is used for placement of the camera (TECH FIG 2A).
- A guidewire is then placed directly over the vertebral bodies over the intended second-most-proximal portal and is visualized with the thoracoscope placed in the anterior portal (TECH FIG 2B).

FIG 3 • Positioning for access for a thoracoscopic anterior spinal fusion and instrumentation in the left lateral decubitus position. The arms are positioned at 90 degrees, axillary rolls are placed on the left axilla, and the patient is secured with a bean bag.

TECH FIG 1 • Fluoroscopic imaging of the spine prior to surgery. A. The lateral radiograph is used to identify the anterior and posterior edges of the vertebral body. B. The AP radiograph is used to mark the skin over the intended fusion levels to direct portal placement. This example demonstrates a T6–T12 fusion.
Part 4 PEDIATRICS • Section VII SPINE

**TECHNIQUES**

- After good placement of the guidewire (directly over the rib head), the portal is placed with a transverse incision centered over the rib. This portal can be used for visualization with a thoracoscope to place the remaining portals.

- The most proximal posterolateral portal is placed after the intended second posterolateral portal to ensure exact location of the proximal portal. The proximal portal position is most important, since the most proximal two screws are often placed in small vertebral bodies and have significant coronal angulation, and retraction of the scapula makes this portal difficult.

- The remaining portals are placed in the posterolateral line.

- The portals will house the camera, a fan retractor to retract the lung, a suction device, a working portal, and then a free portal.

**Discectomy Technique**

- The pleura is incised in the midvertebral line in a longitudinal fashion, keeping the segmental vessels intact (TECH FIG 3A).

- The segmental vessels are then ligated two or three at a time (normotensive anesthesia is used for anterior surgery).

- The parietal pleura is retracted anteriorly, all the way to the opposite side, and access to the anterior longitudinal ligament and the contralateral annulus is allowed (TECH FIG 3B).

- Posterior retraction allows for identification of the rib heads (TECH FIG 3C).

- The disc is incised from the convex rib head to the opposite annulus (TECH FIG 3D).

---

**TECH FIG 2 • A.** The anterior portal is placed in the anterior axillary line with the camera inserted in the portal. The patient is in the left lateral decubitus position: proximal to the right and distal to the left. **B.** A guidewire is placed before placing the posterior lateral portals. The guidewire is directed just anterior to the rib heads and marks a good position for the posterolateral portal.

**Discectomy Technique**

- Electrocautery is used to incise the parietal pleura longitudinally, starting over the disc to avoid the segmental vessels. The segmental vessels are left intact on the first pass. **B,C.** After ligation of the segmental vessels, the pleura is bluntly retracted. **B.** Anterior dissection circumferentially to the opposite side of the pleura. **C.** Posterior retraction of the parietal pleura beyond the rib head. **D.** A scalpel blade is used to incise the annulus from rib head posteriorly all the way to the opposite annulus. Shown here is the incision up against the rib head after incising the annulus and the anterior longitudinal ligament. **E.** Disc shavers are used to break up the disc material. **F.** An angled curette is used to take down the endplate and tease the periosteum around the corner to get full access to the bone. *(continued)*
The rib head is being removed. Electrocautery is used to loosen the soft tissues attaching the rib head to the vertebral body. Part of the rib head has been removed in this photo.

- The periosteum for the proximal and distal vertebra is incised to allow for subperiosteal dissection when the discectomy is performed.
- Disc shavers are used to break up the disc material, using shavers of increasing width (TECH FIG 3E).
- A rongeur is used to remove the annulus and nucleus pulposus.
- An angled curette is used to take down the endplate circumferentially (TECH FIG 3F).

The rib head is removed at the T4–T7 levels. Since it is positioned relatively anterior on the vertebral bodies, it allows for good discectomy and good placement of the screws at these levels (TECH FIG 3G).
- After discectomy, Gelfoam or Surgicel is placed in the disc space to prevent endplate bleeding.

**Implant Placement and Grafting**
- Screw placement is performed beginning at the apex of the curve.
- The proper screw position starts just anterior to the rib head and is angled in line with the midaxial plane of the vertebral body (angled anteriorly at the apex especially, with less angulation at the proximal distal levels) (TECH FIG 4A).
- Screw position should be parallel to the endplate, and the proximal and distal levels should be angled toward the apex of the curve so that during correction, any screw plow will not loosen screws. Visualization of adjacent screws should confirm good alignment (TECH FIG 4B).
- After screw placement, the screw height should be visualized to ensure that rod seating will occur without difficulty (TECH FIG 4C).
- Autologous bone is packed into the disc space after removal of Gelfoam or Surgicel.
- Rod placement is performed; rods can be seated either proximally or distally. Depending on rod flexibility and size, a straight rod is placed on the end and the set screws are engaged to secure the rod (TECH FIG 4D).

The screw-awl device is placed while visualizing a previously placed screw. The starting point is just anterior to the rib head in this photo. **B.** Final placement of a distal screw while visualizing the more proximal screws. The diaphragm is seen in the background. **C.** After screw placement, the height of the screws should be consistent to allow easy seating of the rod. **D.** The rod is inserted into the most distal screws. **E.** Compression across the most distal segment is first performed using the cable compressor. **F.** After distal compression, the rod is cantilevered to the remaining screw heads. (continued)
Compression across the initial levels is then performed to improve the coronal- and sagittal-plane deformity (TECH FIG 4E).

The rod is then cantilevered down to the remaining screws, and compression is sequentially performed over those levels. Often the rod cannot be cantilevered down to all of the screws, so sequential cantilever and compression are performed (TECH FIG 4F).

Radiographs are obtained at this point and the desired correction is compared with the radiographs. Further compression is performed as needed. Care should be taken to ensure that screw plow or loosening is not occurring radiographically or visually (TECH FIG 4G,H).

Set screws are completely torqued down.

The pleura is closed over the instrumentation to ensure correct bone graft positioning, decreased chest tube drainage, and improved long-term pulmonary function (TECH FIG 4I).

The lung is inflated under direct visualization.

A chest tube is placed through the distal portal incision and tunneled to the proximal portal (TECH FIG 4J).

The incisions are closed in the normal fashion.

### OPEN INSTRUMENTATION AND ARTHRODESIS OF THE THORACOLUMBAR–LUMBAR SPINE

#### Preparation and Exposure

- The patient is placed in the lateral decubitus position with the convex side of the spine up.
- An axillary roll is placed.
- The bed is flexed to allow for easier access to the flank (TECH FIG 5A).
- A curved linear incision is made in line with the rib just proximal to the planned upper instrumented vertebra (TECH FIG 5B).
- The incision is carried down through the subcutaneous layer through the various muscle layers down over the rib. The incision can be carried out distally lateral to the umbilicus.
- Subperiosteal dissection is carried out around the rib. The rib is transected posteriorly near its insertion to the spine (TECH FIG 5C).
- The costochondral junction is then incised. A marking suture is placed at the costochondral junction for later reapproximation (TECH FIG 5D).
- Usually at the costochondral level at the 10th rib, access into the retroperitoneal space is quite easy, with retroperitoneal fat evident. The peritoneal contents are then bluntly dissected off the abdominal wall and the undersurface of the diaphragm (TECH FIG 5E).
- The diaphragm is then incised just proximal to its insertion, and marking sutures are placed to ensure proper reapproximation (TECH FIG 5F).
- A pleural incision is made longitudinally in line with the spine, leaving the segmental vessels intact (TECH FIG 5G).
- Segmental vessel ligation is then carried out, maintaining good blood pressure to ensure good spinal cord perfusion (TECH FIG 5H).
**TECH FIG 5** • **A.** Positioning for thoracoabdominal approach to the spine. The table is flexed to allow full access to the thoracoabdominal region. **B.** Skin incision is marked. This example is centered over the 10th rib for a T11–L3 fusion. **C.** The incision is made over the rib and subperiosteal dissection is carried out circumferentially around the rib after sequential dissection through the musculature. **D.** The posterior aspect of the periosteum is then incised and the chest is entered. **E.** After incision of the costochondral junction, the retroperitoneal fat is visualized and the retroperitoneal cavity is entered. **F.** The diaphragm is incised a fingerbreadth proximal to its insertion. **G.** The parietal pleura is incised proximally. **H.** Ligation of segmental vessels after suture tying.
Discectomy

- Discectomies are performed with incision of the annulus fibrosis (TECH FIG 6A).
- Endplate dissection is carried out, using a Cobb elevator to remove the entire endplate disc material back to the posterior aspect of the annulus and to the posterior longitudinal ligament if necessary (for severe curves; TECH FIG 6B).
- The disc material is removed completely using rongeurs and curettes (TECH FIG 6C).
- The disc space is packed with Surgicel.

Implant Placement, Correction, and Fusion

- The instrumentation is then placed using single large screws with a quarter-inch single-rod implant system, or a dual rod with a 5.5-mm rod (shown here).
- Screws are initially placed at the apex in the middle to posterior third of the vertebral body in the midaxial plane (TECH FIG 7A).
- When using a dual-rod system, the posterior screws are initially placed angled in the midaxial plane, while the anterior screws are directed slightly posteriorly. A staple is often used when both the single- and dual-rod screws are used (TECH FIG 7B).
- Once screws are placed, the bone graft material is placed as far back toward the posterior longitudinal ligament as possible, or the posterior rim of the annulus fibrosis.
- The operating table should now be leveled to allow for correction of the spine.
- The posterior rod is initially placed with the dual-rod system, and a 90-degree rod rotation removal can be performed (TECH FIG 7C).
• Alternatively, directed force on the anterior screws to correct the coronal and axial plane is achieved, and then the posterior rod is inserted (TECH FIG 7D).
• After rod rotation with a dual-rod system or single-rod system, or correction with pressure on the anterior screws and fixation with the posterior rod, the anterior structural support is placed. This is most commonly at levels distal to T12 or alternatively at all instrumented levels (TECH FIG 7E).
• Compression can then be performed to further correct coronal-plane deformity.
• The anterior structural support should be placed anteriorly and onto the concavity to ensure maintenance of the lordosis and improvement of coronal-plane correction.
• The second anterior rod should be then placed with a dual-rod system and all set screws completely tightened (TECH FIG 7F).

 Closure

• The remaining bone graft material is then placed in the remaining disc space.

 TECH FIG 7 • (continued) C. Insertion of the posterior rod with lumbar lordosis built into the rod. D. After 90 degrees of rod rotation, scoliosis correction is achieved while restoring lumbar lordosis, as shown here. E. After rod rotation, the anterior structural support is placed anteriorly and toward the concavity of the deformity. F. The anterior rod is seated into the anterior screws.

• The pleura is closed as far distally as possible (TECH FIG 8A).
• The diaphragm is reapproximated with interrupted Neurolon sutures (TECH FIG 8B).
• The costochondral junction is reapproximated, and the periosteum of the rib is reapproximated (TECH FIG 8C).
• A chest tube of fairly large diameter is then placed.
• The abdominal wall is reapproximated in layers (TECH FIG 8D).
• The remaining muscle layers are closed, as well as the skin and subcutaneous layers (TECH FIG 8E).
• The postoperative radiographs are shown in TECHNIQUES FIGURE 8F AND 8G.

 TECH FIG 8 • A. The parietal pleura is closed beginning proximal to the implants. B. Interrupted Neurolon sutures are used to close the diaphragm in an anatomic fashion. (continued)
TECH FIG 8 • (continued). C. The ribs are reapproximated after placing no. 1 sutures under the proximal and distal ribs. D. Sequential closure of the muscle and soft tissue layers. E. Skin closure. F,G. The patient in Figure 1, 1 year postoperatively.

**PEARLS AND PITFALLS**

**Anesthesia**
- During anterior surgery, normotensive anesthesia should be performed to maintain spinal cord perfusion, especially when segmental vessel ligation is performed.
- Complete discectomy is necessary to achieve fusion since pseudarthrosis rates continue to be higher with anterior surgery than with posterior surgery.

**Camera performance**
- Thoracoscopy requires outstanding visualization and camera performance to ensure safe and effective discectomy, as well as instrumentation.

**Rib head removal**
- Rib head removal during thoracic instrumentation from T4 to T7 is necessary to ensure screws are placed posteriorly enough to achieve good purchase.

**Discectomy**
- This is the most important aspect of the procedure to mobilize the spine for correction and to achieve a solid arthrodesis.

**Screw placement**
- Screw placement is always challenging at the proximal and distal levels. Screw trajectories should always be parallel to the endplate, or if anything angled toward the apex of the curve, so that during correction plowing does not result in loosening of the screw.

**Deformity correction**
- Thoracic curve: Compression at sequential levels, followed by cantilever of an undercontoured rod, followed by further compression
- Thoracolumbar–lumbar curve: Rod rotation followed by compression
POSTOPERATIVE CARE

- The chest tube should be placed to wall suction and can usually be removed between 48 and 72 hours, when the drainage decreases below 80 cc per shift and when it turns more straw-colored.
- Serial hemoglobin and hematocrit levels should be obtained in the first 48 hours.
- Advancing activities: Sitting in a chair the first postoperative day and walking on the second postoperative day ensures good postoperative pulmonary status and normal bowel function.
- Postoperative bracing is used for 3 months for single-rod anterior thoracoscopic thoracic arthrodesis and instrumentation. No bracing is necessary with single quarter-inch rod instrumentation or dual-rod instrumentation when anterior structural support is used.
- Normal activities are resumed when arthrodesis is visualized (best seen on the lateral radiograph).

OUTCOMES

- Thoracoscopic anterior instrumentation and fusion achieves a good radiographic and functional outcome.
- Thoracoscopic anterior instrumentation and fusion continues to have a fairly high pseudarthrosis rate of 5% to 6%.
- Pulmonary function is somewhat decreased early in the postoperative period with anterior surgery, but then it can return to baseline at 1 to 2 years.
- Thoracolumbar–lumbar anterior instrumentation and fusion results in excellent coronal-, axial-, and sagittal-plane realignment, especially when dual-rod and large single-rod instrumentation systems with anterior structural support are used.

COMPLICATIONS

- Acute complications
  - Infection is rare in anterior spine deformity surgery.
  - Atelectasis and mucous plugs can be seen, especially with single-lung ventilation with anterior instrumentation. Aggressive pulmonary toilet and resuming activities minimize this risk.
- Late complications
  - Pseudarthrosis: The incidence is 4% to 10% for thoracic scoliosis (usually occurs at the apex of the curve) and 4% to 12% for thoracolumbar scoliosis (usually occurs at the distal fusion level).
  - Loss of correction with kyphosis is seen for thoracolumbar–lumbar curves treated anteriorly when anterior structural support is not used.

REFERENCES

DEFINITION
- Thoracoscopy provides the ability to gain access to the thoracic spine via small incisions (portals).
- *Anterior release* includes removal of the annulus fibrosis, anterior longitudinal ligament, nucleus pulposus, and, if necessary, the rib head.
- *Scoliosis* is a lateral curvature of the spine with axial plane rotation.
- *Fusion* is the healing of two vertebral bodies together, usually fused by bone graft or bone graft substitute.

ANATOMY
- The thoracic spine spans from the first thoracic vertebra (T1) to the twelfth thoracic vertebra (T12).
- The rib head attachment to the vertebral body is more anterior in the proximal thoracic spine than the distal thoracic spine.
- The annulus fibrosis is the circumferential fibrous tissue that surrounds the nucleus pulposus, which is in the center of the disc.
- The anterior longitudinal ligament, which runs on the anterior aspect of the vertebral body, is a strong fibrous tissue that is contiguous throughout the spine. The segmental arteries and veins originate from the aorta and vena cava, respectively, and traverse the vertebral body. The parietal pleura of the chest surrounds the thoracic spine, covering the segmental vessels and the disc and vertebral bodies. The anterior, middle, and posterior axillary lines run (in reference to the axilla) in the anterior, middle, and posterior aspects of the axilla. Scoliotic deformity in the thoracic spine is lateral curvature with axial plane rotation, as well as hypokyphosis (idiopathic scoliosis).
- The arch of the aorta and the arch of the azygous vein typically are located at the T4–T5 levels.

PATHOGENESIS
- Scoliosis can be grouped into many categories based on pathogenesis.
- The most common type of scoliosis seen is idiopathic, in which the etiology and pathogenesis are unknown.
- Theories of pathogenesis include hormonal influences, growth disturbance, genetic factors, muscle imbalance, and proprioception and balance abnormalities.
- Other types of scoliosis include:
  - Congenital: abnormal vertebra due to failure of formation or segmentation
  - Neuromuscular: eg, cerebral palsy, Duchenne muscular dystrophy, spinal muscular atrophy
  - Neurogenic: eg, neurofibromatosis, spinal cord injury

NATURAL HISTORY
- An idiopathic scoliosis curve may progress in two ways:
  - With continued spine growth
  - When curve magnitude is greater than 50 degrees at skeletal maturity
- Curve progression can be rapid during spine growth, or slow following skeletal maturity (approximately 1 degree per year).
- Curve magnitudes above 80 to 90 degrees in the thoracic spine may result in symptomatic pulmonary issues.
- Large curves in adulthood can result in pain.¹

PATIENT HISTORY AND PHYSICAL FINDINGS
- The examination for spine deformity should include standing visualization of the spine to look for shoulder height differences, waist asymmetry, overall trunk balance, or coronal head imbalance (FIG 1).
- Further information is obtained as to the character of the pain (eg, sharp, dull, aching), when the pain occurs (eg, during activity, while attempting to sleep, pain waking from sleep), and the location of the pain (eg, upper, middle, lower back), as well as whether it radiates into the lower extremities.
- Other history should include any information on other neurologic symptoms such as bowel or bladder incontinence.
- Sensory symptoms should be elicited, especially with hyperesthesias along the chest wall, or upper or lower extremities.
- Cutaneous manifestations of dysraphism should be analyzed.
- The neurologic examination should include motor strength and a sensory examination of the upper and lower extremities.
- The abdominal reflexes are the most important neurologic assessment. They are assessed by stroking the skin adjacent to the umbilicus on the left and right and upper and lower quadrants, and should be symmetrically absent or present. When asymmetric, MRI is necessary to evaluate for neural axis abnormalities.
- The lower extremities should be carefully examined for asymmetry with respect to size and strength of the legs, as

FIG 1 • This 9-year-old boy had a left-sided large thoracic scoliosis but no evidence of neural axis abnormalities on preoperative MRI.
well as foot deformities (eg, cavovarus foot deformities) as an indication for the presence of neural axis abnormalities.
- Deep tendon reflexes and the Babinski reflex should be investigated.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiography should include a standing posteroanterior (PA) and lateral radiograph of the spine to include the cervical spine to the pelvis and hips.
- The PA radiograph (FIG 2A) should be evaluated for:
  - Coronal plane deformities using the Cobb method
  - The C7–center sacral vertebral line (CSVL) placement
  - A trunk shift using Floman’s method (the distance between the CSVL and the mid-distance between the lateral rib margins)
  - Evaluation for any congenital abnormalities (eg, hemivertebra, congenital bar)
  - The Risser stage (0 through 5)
  - The status of the triradiate cartilage (open or closed)
- The lateral radiographs (FIG 2B) should be analyzed to determine:
  - Thoracic kyphosis and lumbar lordosis
  - Presence of associated spondylolisthesis or spondylolysis
  - Sagittal balance (distance between C7 plumb line and the posterior edge of the first sacral vertebral body)
  - The Stagnara view is an oblique view to the patient, but an orthogonal view to the coronal curve that is used in severe spinal deformities to better visualize the spine.
- Indications for MRI include neurologic abnormalities, significant back pain associated with scoliosis, atypical curve patterns such as a left thoracic curve, very young age, congenital scoliosis, neurofibromatosis, Marfan disease.
- CT scanning may be useful to fully define the osseous anatomy, especially for extremely large curves and congenital curves.

DIFFERENTIAL DIAGNOSIS
- Idiopathic scoliosis
- Congenital scoliosis
- Neurofibromatosis
- Scoliosis associated with Marfan disease

NONOPERATIVE MANAGEMENT
- Nonoperative management has little or no role for severe deformity.
- Patients who are very young with moderate deformity may be treated with a brace to buy time to allow the patient to grow.
- Bracing can be effective to prevent curve progression for small idiopathic curves (ie, 25 to 40 degrees).

SURGICAL MANAGEMENT
- Anterior thoracoscopic release for spinal deformity has many technical considerations, which are discussed later in this chapter.
- Indications for an anterior release/fusion
  - Severe spinal deformity: scoliosis greater than 80 to 90 degrees with significant rotational deformity or kyphosis greater than 100 degrees with flexibility index less than 50%
  - Skeletal immaturity, to avoid the crankshaft phenomenon. Usually performed for children younger than 10 years of age with open triradiate cartilage and Risser grade 0.
  - Deficient posterior elements, so that a posterior fusion may be difficult. Such deficiencies occur secondary to previous surgery with laminectomies for tumors or the treatment of neural axis abnormalities.

Preoperative Planning
- Each patient should be carefully analyzed with respect to those curves that will undergo an anterior release.
- The radiograph should be viewed to determine preoperatively which levels should be released. Release always includes the apical levels, and usually includes all of the levels within the Cobb measurement.
- For severe curves, traction in the operating room may be helpful in assisting curve correction.

Positioning and Approach

Lateral Position
- Advantages
  - More familiar and traditional approach
  - Conversion to open procedure is easy.
  - All thoracic levels can be accessed.
  - One can effectively obtain access to the T1 to T5 levels, which are not accessible when the patient is in the prone position.
- Disadvantages
  - Repositioning is necessary for the posterior approach.
  - Single-lung ventilation is required.
- Approach
  - Single-lung ventilation is achieved with a double-lumen endotracheal tube or a univent tube.
  - Position the patient in the lateral decubitus position.
  - Check the endotracheal tube position and the single-lung ventilation status.
  - Prepare and drape the chest and side (FIG 3).
  - Place four portals in the anterior axillary line.
Prone Position

Advantages
- Not necessary to reposition patient for the posterior procedure
- No need for single-lung ventilation
- Significantly decreased respiratory complications. Single double lung ventilation is used.

Disadvantages
- Difficult to obtain an anterior release proximal to T5.
- Conversion to open procedure is difficult.

Approach
- Placement of regular endotracheal tube
- Double-lung ventilation with decreased tidal volumes (about 50% to 60% of normal) and increased ventilatory rate
- Placement prone on a spine frame (FIG 4A,B)
- Ensure access to the flank and chest.
- Prepare and drape the back and the chest and flank (FIG 4C,D).

Thoracoscopic Release and Fusion for Scoliosis

Placement of Portals and Visualization
- Place portals as anteriorly as possible, usually in the midaxillary line (TECH FIG 1A,B).
- Insert the camera into the initial portal with the lens directed posteriorly (TECH FIG 1C).
- Find a clear space between the posterior chest wall and the lung and advance the thoracoscope.
- Place a small, blunt-tipped cottonoid to retract the lung, to identify the spine and other anatomic structures.
- Place a fan retractor to fully retract the lung, if necessary (TECH FIG 1D).
- Place suction into the chest.
- Place working portal.
- Visualize the spine in the horizontal plane with the segmental vessels intact (TECH FIG 1E).
Exposure and Disc Removal

- Incise the pleura along the mid-vertebral body line (TECH FIG 2A).
- Spare the segmental blood vessels to preserve perfusion to the spinal cord.
- Bluntly retract the pleura anteriorly and posteriorly (TECH FIG 2B).
- Incise the annulus fibrosis with the scalpel blade circumferentially from lateral rib head to near-opposite rib head (TECH FIG 2C).
- Break up the disc with disc shavers (TECH FIG 2D).

- Remove the disc material with a rongeur (TECH FIG 2E).
- Take down the endplate with a curved curette (TECH FIG 2F).
- Place Surgicel (Ethicon, Inc., Somerville, NJ) or other thrombotic agent.
- Remove the disc from all levels planned.
- Place bone graft if desired (TECH FIG 2G).
- Close the pleura using the Endostitch device (US Surgical, Warsaw, IN), running one suture from proximal and one from distal (TECH FIG 2H–J).
- Place a chest tube (TECH FIG 2K).
- Close the portal incisions.

(a) Using a curved electrocautery blade, the pleura is incised in the longitudinal fashion, sparing the segmental vessels. (b) The parietal pleura is retracted anteriorly, as shown, to allow for complete access to the anterior longitudinal ligament, as well as the opposite annulus. The posterior pleura is also retracted. (c) The annulus is incised parallel to the disc. (d) Disc shavers are used to break up the disc material. (continued)
E. The disc material is removed with a rongeur. F. The endplate is taken down to bone with an angled curette. G. Bone graft is placed. H–J. The pleura is closed with an Endostitch device. H. Closure is started distally with a running suture. I. Final closure of the pleura, in which the proximal suture is brought to the distal suture. J. The pleura is closed nicely with a running suture. K. Placement of the chest tube at the completion of the procedure, from distal to proximal. The lung is still deflated. The pleura, seen in the background, has been closed previously.

PEARLS AND PITFALLS

**Portal placement**
- Placement of portals is key for visualization and achieving good discectomy.
- Place the skin incision for the portal over a rib to allow the portal to be placed above and below the rib (two portals per skin incision).
- Ensure that portals are neither too posterior nor too anterior.

**Preservation of segmental blood vessels**
- Incise the pleura in a longitudinal fashion, staying superficial to the segmental vessels.
- Use a curved harmonic scalpel or electrocautery.
- Incise any adventitial tissue adherent to the pleura over the disc to free up the parietal pleura.
- Bluntly retract the pleura to gain access to the disc.

**Complete removal of the disc**
- Develop the same sequence for disc removal:
  1. Incise the disc with a scalpel blade.
  2. Break up disc material with shavers.
  3. Remove loosened disc material.
  4. Take down the endplates of the vertebral bodies with a curved curette.
  5. Remove excess endplate material.

**Pleural closure**
- Use the Endostitch device with 2-0 Vicryl suture.
- Use two sutures: the first begins in the proximal aspect and is run distally, and the second is started distally and is run proximally.

POSTOPERATIVE CARE

- Chest tube management
  - Connect chest tube to wall suction.
  - Obtain daily chest radiographs.
  - The chest tube may be removed when drainage is less than 80 mL over 12 hours and serous color returns (with good pleural closure, removal usually is done on the first day).
- Mobilize the patient to chair on postoperative day 1.
- Mobilize the patient to ambulation when the chest tube is removed (usually postoperative day 2).
- Serial hemoglobin and hematocrit on postoperative days 1 and 2
- Advanced activities as tolerated to daily activities in the initial 6 weeks
For the following 6 weeks, physical activities are advanced, depending on posterior constructs.

OUTCOMES
- The addition of a thoracoscopic anterior release and fusion results in a decrease in pulmonary function in the first 6 weeks; however, at 1 year it is 30% above baseline.
- Anterior release increases the flexibility of the spine and allows for great coronal, axial plane, and sagittal plane correction.
- With good surgical technique, an outstanding anterior release can be achieved and will allow for exceptional three-dimensional correction of the spine with posterior instrumentation and fusion (FIG 5).

COMPLICATIONS
- Single-lung ventilation
- Intraoperative complications: inability to ventilate adequately secondary to ventilation-perfusion mismatches, high airway pressures and barotrauma, and underlying pulmonary issues
- Postoperative complications: atelectasis secondary to barotrauma or mucous plugs
- Continuous chest tube drainage, especially when the parietal pleura has not been closed
- Pneumothorax following chest tube removal
- Intraoperative injury to the segmental blood vessels or the great vessels
- Intraoperative injury to the thoracic duct, which usually occurs on the right side at the T11–12 area. This can be avoided by dissection deep to the parietal pleura.
- Chylothorax is treated with total parenteral nutrition and avoidance of a fatty diet.
- Intraoperative excessive bleeding secondary to inadvertent segmental vessel injury. Strategies to coagulate the vessel are used.
- Long-term complications secondary to a thoracoscopic anterior release and fusion are limited.

REFERENCES

FIG 5 • The 2-year postoperative AP and lateral radiographs of the patient shown in Figures 1 and 2 demonstrated outstanding coronal and sagittal plane correction after prone thoracoscopic anterior release and fusion followed by a posterior spinal fusion and instrumentation from T2 to L2.
DEFINITION

- Neuromuscular spinal deformity is a result of an abnormal neuromuscular system in childhood, as in cerebral palsy, muscular dystrophy, spinal muscular atrophy, and so forth. It may be related to a pathologic abnormality in muscle tone, motor control, or weakness or a combination.
- While neuromuscular scoliosis (coronal deformity) is the most common neuromuscular spinal deformity, sagittal plane deformity (hyperlordosis and hyperkyphosis) may also occur.

ANATOMY

- The curve patterns of neuromuscular scoliosis are most commonly lumbar or thoracolumbar with associated pelvic obliquity (FIG 1).
- Since many children are nonambulatory, associated pelvic obliquity affects sitting balance.
- Ambulatory neuromuscular patients often have decompensation, with the inability to center their head over the center sacral line.

PATHOGENESIS AND NATURAL HISTORY

- The biologic basis of scoliosis or sagittal plane spinal deformity in neuromuscular disorders differs depending on the cause of the specific neuromuscular disease. In general, however, most neuromuscular spinal deformities are largely due to muscle imbalance (low tone or high tone) and abnormal postural reflexes.
- The natural history of neuromuscular scoliosis is usually that of slow progression, beginning with the development of a flexible scoliosis in middle childhood and the more rapid development of a more fixed scoliosis during the adolescent growth spurt. Some neuromuscular conditions are associated with a more progressive scoliosis than others.
- The clinician must weigh the progressive characteristics of scoliosis within each neuromuscular disease with the natural history of the disease itself when deciding on treatment.
- The pathogenesis and natural history of some of the more common disorders associated with neuromuscular spinal deformity and spinal deformity within the disease follow.

Cerebral Palsy

- Cerebral palsy is a heterogeneous disorder that is characterized by a static lesion (e.g., injury, congenital defect) to the immature motor cortex of the brain. In modern society, it has become the most common cause of neuromuscular spinal deformity.
- The natural history of neuromuscular scoliosis in cerebral palsy is frequently that of progression. The rate of progression can be very severe in adolescent years (2 to 4 degrees per month).
- Progression also occurs after skeletal maturity, and in curves greater than 40 degrees it may occur at a rate of 2 to 4 degrees per year.¹⁶
- Curves in the 60- to 90-degree range begin to affect sitting, arm control, and head control. Further progression may prevent the child from sitting in an upright position.
- Conservative treatment with chair modifications and bracing is only a temporary treatment and does not stop curve progression. Conservative treatment is especially helpful in the younger child with a flexible scoliosis to temporarily maintain upright sitting posture. This will allow the spine to grow to its maximum size so that the resulting fusion can correct the spinal deformity without limiting growth.

Muscular Dystrophy

- Duchenne muscular dystrophy is a sex-linked recessive disorder involving a defect on the Xp21.2 locus of the X chromosome resulting in a marked decrease or absence of the protein dystrophin.⁵
- Affected children become progressively weaker with age, eventually becoming nonambulatory.
- Death typically occurs in the second or third decade secondary to pulmonary or cardiac failure.
- Scoliosis is almost universal when the child becomes nonambulatory, and curve progression correlates strongly with a decline in respiratory function.
- The prevalence of scoliosis approaches 100%.¹⁴ For this reason, surgery is done soon after the child becomes nonambulatory, before an irreversible decline in forced vital capacity occurs.

Myelomeningocele

- Myelomeningocele, a congenital malformation of the nervous system, is due to a neural tube defect and results in a spectrum of sensory and motor deficits.
While the level of the spinal cord defect influences the clinical presentation of the disease, neurologic deterioration may occur at any age owing to hydrocephaly, hydrosyringomyelia, Arnold–Chiari deformity, and tethered cord syndrome.

In general, the higher the level of the defect, the higher the prevalence of scoliosis. Almost 100% of thoracic-level paraplegic patients will develop scoliosis. A long C-shaped curve is associated with a high level of paralysis and usually occurs at a young age.

Hydromyelia and tethered cord syndrome may also be associated with scoliosis and should be suspected if the scoliosis onset is more sudden and associated with other symptoms of acute neurologic deterioration.

Bracing in younger children can be attempted to slow progression, but it does not stop eventual progression.

**Spinal Muscular Atrophy**

This condition is an autosomal recessive disorder resulting in spinal cord anterior horn cell degeneration. Two genes on the chromosome 5q locus have been found to be associated with this disorder: survival motor neuron gene (SMN) and neuronal apoptosis inhibitory gene (NAIP). Clinically, progressive muscular weakness occurs, and eventual pulmonary compromise is common.

Three forms of this disease exist:
- Type 1 (early, acute Werdnig–Hoffmann)
- Type 2 (intermediate, chronic Werdnig–Hoffmann)
- Type 3 (late, Kugelberg–Welander type)

Most children with the early form of the disease die at an early age and therefore do not require treatment.

Most children with the intermediate and late type who survive into adolescence develop a progressive spinal deformity. The curvature typically starts in the first decade. Thoracolumbar and single thoracic patterns are most common.

One third of patients have an associated kyphosis in the sagittal plane. Bracing is ineffective at preventing curve progression but may delay progression in the very young patient to allow further growth of the spine.

**Friedreich Ataxia**

This autosomal recessive disorder results in a slowly progressive spinocerebellar degeneration. A defect on chromosome 9 has been identified.

The incidence of scoliosis is 100%, and progression is related to the age of disease onset. When disease onset is prior to age 10 years and scoliosis onset is before 15 years, scoliosis progression is usually greater than 60 degrees.

Prophylactic bracing may be effective in smaller curves (under 20 degrees). There are no data to support that bracing is effective in preventing progression in established curves greater than 20 degrees.

**Rett Syndrome**

This is an X-linked disorder that affects females almost exclusively. Some children have a mutation on the MECP2 gene. The child’s development is normal until 6 to 18 months of age, followed by a rapid deterioration in cognitive and motor function.

After the initial deterioration in function, the neurologic picture may become relatively static for years. The clinical spectrum is variable, with some children remaining ambulatory and others becoming wheelchair-bound.

Rett syndrome may be mistaken for cerebral palsy.

Scoliosis has been reported in up to 80% of patients. A long C-shaped thoracolumbar pattern is common. Bracing is typically ineffective and curve progression is common. Surgical stabilization allows maintenance of sitting balance.

**Spinal Cord Injury**

Spinal cord injury in the skeletally immature child is associated with a nearly 100% incidence of scoliosis.

The predominant curve type is a long C-shaped curve. The younger the child, the higher the progression.

Prophylactic bracing may be effective in smaller curves (under 20 degrees). There are no data to support that bracing is effective in preventing progression in established curves greater than 20 degrees.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

The medical history is critical for this group of patients.

In patients with cerebral palsy, the medical history correlates very strongly with postoperative complications. This appears to be true also in patients with Duchenne muscular dystrophy and spinal muscular atrophy.

Important historical information includes respiratory status, cardiac status, gastrointestinal status (eg, gastroesophageal reflux, nutritional intake), and the presence of a seizure disorder.

Physical examination should assess sitting or standing balance, the pelvic obliquity, and curve magnitude and stiffness (including the curve’s coronal, sagittal, and rotational components).

Coronal plane stiffness is best assessed by performing the side-bending test (FIG 2).

The physician should also assess for the possible coexistence of hip subluxation or dislocation, which is common in many neuromuscular diseases.

A complete neurologic examination should also be performed.

**FIG 2** Side-bending test. Patient is being bent over the examiner’s thigh at the apex of the curve. If the patient’s curve reverses and the pelvis levels to perpendicular to the trunk, the curve is still flexible enough to correct through posterior fusion and instrumentation alone. If not, an anterior release is performed.
IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior (AP) and lateral radiographic views should be obtained to assess the Cobb angle and pelvic obliquity in the coronal plane, and lumbar lordosis and thoracic kyphosis in the sagittal plane.
- If intraspinal pathology is suspected, especially in the ambulatory patient, a preoperative magnetic resonance imaging (MRI) scan should be obtained.

DIFFERENTIAL DIAGNOSIS

- Some neurologic diseases can look similar.
- It is important to diagnose progressive neurodegenerative disorders in which mortality from the disease is more rapid than the progression of the spinal deformity.

NONOPERATIVE MANAGEMENT

- While there was initially some historical enthusiasm for the treatment of neuromuscular scoliosis with casting or bracing, orthotic management has been found to have little or no impact on neuromuscular deformity.
- Flexible curves in younger children may require seating modifications (hip guides and offset lateral seat supports) or a soft thoracolumbar orthosis to maintain balanced seating until the child is at optimal sitting height.
- Orthotic treatment does not affect the rate and eventual progression of neuromuscular scoliosis.

SURGICAL MANAGEMENT

Indications

- The indications for spinal fusion in neuromuscular scoliosis depend largely on the natural history of the specific neuromuscular disease and the natural history of the scoliosis within the specific disorder.
- Examples of two neuromuscular diseases with different indications are Duchenne muscular dystrophy and cerebral palsy.

Duchenne Muscular Dystrophy

- The major comorbidity in Duchenne muscular dystrophy is a restrictive type of pulmonary involvement, with forced vital capacity dropping dramatically with scoliosis progression.
- Due to the natural history, the indication for fusion is a scoliosis curvature greater than 25 degrees and forced vital capacity greater than 35%.

Cerebral Palsy

- The indications for spinal fusion in children with cerebral palsy are a scoliosis curve magnitude approaching 60 degrees in the older child, especially if the curve is becoming stiff by physical examination.
- Surgical correction is indicated when the child is not tolerating seating with a combination of either seating adjustments or a soft orthosis.
- Less commonly, sagittal plane spinal deformity, hyperlordosis, and kyphosis will cause seating problems or back pain. Cerebral palsy patients with sagittal plane spinal deformity of 70 degrees or more causing seating difficulties or back pain can also benefit from surgical correction.
- Typically during the middle part of adolescent growth, the scoliosis becomes much larger and begins to progress and stiffen. Surgical instrumentation and fusion is recommended at this time.

Preoperative Planning

Technical Considerations

- Two main technical preoperative questions require careful consideration:
  - Is fusion to the pelvis necessary?
  - Is an anterior release (discectomies around the stiff portion of the curve) necessary?
- The only treatment that has made a definitive impact on neuromuscular spinal deformity is instrumentation and fusion.
- The standard surgical procedure for neuromuscular scoliosis is a posterior spinal fusion with segmental instrumentation from T1 or T2 down to the sacrum if there is pelvic obliquity.
- Even if the pelvis is not involved in a severely involved non-ambulatory patient or an ambulatory patient with a poor “righting reflex,” the surgeon should still consider fusion to the pelvis to prevent the development of late pelvic obliquity.
- Some children with Duchenne muscular dystrophy who have no pelvic obliquity are an exception and can be treated with fusion ending at L5.
- The gold standard for neuromuscular scoliosis is Luque rod instrumentation (with Galveston extension for the pelvis), cross-linkage to prevent rod shift and rotation, and sublaminar wires.
- The unit rod incorporates these concepts into one instrumentation system

FIG 3 • A. The unit rod is available commercially in a range of sizes. B. Drill guides are provided for placement of the pelvic limbs as well as the impactor and pusher for the rod. (continued)
The unit rod is especially powerful as a cantilever to correct pelvic obliquity (FIG 3C–E).

Anterior release for scoliosis is required for larger stiff curves that do not bend out on the bending test (generally greater than 90 degrees) (FIG 3F).

Anterior release is also recommended for severe hyperlordotic and hyperkyphotic spinal deformities.\(^8\)

**Other Preoperative Considerations**

- The general medical condition of the child should always be considered first. Many children with neuromuscular conditions will have comorbidities such as pulmonary disease, cardiac disease, seizure disorder, poor nutrition, and so forth.
- All patients with complex preoperative medical conditions should have the appropriate preoperative workup.
- The surgeon and anesthesiologist should plan for the possibility of large intraoperative blood loss.
- Type- and cross-matched blood (up to twice the patient’s blood volume), fresh-frozen plasma, and platelets should be available.
- Good vascular access is required, often through central venous access.
- Another consideration is the use of spinal cord monitoring, the role of which is unclear in many patients with neuromuscular scoliosis. On the one hand, most children with neuropathies and myopathies can be monitored, while most severely retarded quadriplegic cerebral palsy patients with poor motor function cannot be reliably monitored. In addition, it is hard to justify removing implant hardware if there are signal changes in the child with minimal motor function since the risk of a repeat operation to reimplant hardware is quite high in this population.
- As a general rule, any child with ambulatory or functional standing (able to assist with standing transfers) should have somatosensory and motor evoked potential monitoring attempted. There may also be some efficacy in monitoring neuromuscular patients with intact sensation and bowel and bladder control.
- A final preoperative consideration is the bone density of the child undergoing spinal fusion. The child who is nonambulatory, poorly nourished, and on seizure medication is at highest risk. Children with low bone density may be difficult to instrument owing to the possibility of sublaminar wires pulling through or screws pulling out of osteopenic bone.
- Any nonambulatory child with a history of low-impact long-bone fracture should be checked for low bone density using dual-energy x-ray absorptiometry (DEXA scan).
- Children on seizure medication should have calcium, phosphorus, and vitamin D levels measured.
Patients with bone density two or more z-scores below the mean should be considered for treatment using intravenous pamidronate.

Positioning
- The patient is positioned prone on a Jackson table (a Relton–Hall frame can also be used) with the abdominal area free (FIG 4).

EXPOSURE
- A posterior approach to the spine is performed from T1 to the sacrum.
- A complete subperiosteal exposure of each vertebra is performed, followed by exposure of the outer wing of each iliac crest down to the sciatic notch and the bottom tips of the posterior superior iliac spines.

PELVIS PREPARATION
- A drill hole is made between the outer and inner cortex of the ilium with a drill bit. Before drilling, the drill bit is marked 10 mm past the drill guide’s hook for the sciatic notch in children less than 45 kg and 15 mm past the hook in children greater than 45 kg.
- The right or left drill guide is next inserted into the right or left sciatic notch, respectively.
- The lateral handle of the drill guide is placed parallel to the pelvis (iliac crests) while the axial handle is held parallel to the body axis.
- The pelvis is drilled from the inferior tip of the posterior superior iliac spine in a line just superior and anterior to the sciatic notch, where the bone is densest (TECH FIG 1).
- The hole is probed to make certain that the pelvic cortex or the sciatic notch is not penetrated.
- The drill hole can be temporarily packed with Gelfoam to control bleeding.
LUQUE WIRE PASSAGE

- After the spine is completely exposed and pelvis is prepared, the spinous processes are completely removed and the ligamentum flavum is carefully removed to expose the sublaminar spaces.
- Double Luque wires are bent (prebent wires are also available) and passed under the lamina from the lamina of L5 up to and including the T1 lamina.
- The radius of curvature for the wire bend must approximate the width of the laminae to allow safe passage of the wire.
- Two double wires are passed at the L5 and the T1 lamina only, while a single wire is passed at each of the other levels (TECH FIG 2A–E).
- Wires are pulled to equal length and next bent, with the midline bent flat down onto the spinous process beds and the beaded end flat down onto the paraspinous muscles (TECH FIG 2F).
- This helps the wires from getting inadvertently pushed into the spinal canal and allows for easier wire organization.

TECH FIG 2 • When passing wires, it is important to roll the wires under the lamina (A–D), being careful not to catch the tip under the lamina (E), which will lever the wire into the canal and place pressure on the spinal cord. F. Wires are bent down to the midline in the middle and the ends are bent down flat against the paraspinous muscles.
ROD SELECTION AND INSERTION

- After the wires are passed, the length of the unit rod is selected.
- This is done by placing the rod upside down with the corner of the rod placed at the drill hole on the elevated side of the pelvis (TECH FIG 3A).
  - The proper-length rod should reach T1 (TECH FIG 3B).
  - A rod one length shorter should be chosen if there is severe kyphosis because the spine shortens with correction.
  - With severe lordosis, a rod one length longer should be chosen because the spine lengthens with correction.
- It is best to err on the side of the rod being too short because the wires can be brought down to the rod several levels if necessary.
- If the rod is more than 2 cm long, it may be too prominent under the skin.
- In such cases, cutting the rod and cross-linking the rod may be advisable.
- Facetectomy and decortication of the transverse processes are performed. Corticocancellous allograft (crushed) bone is added (about 180 to 240 mL).
- Insertion of the rod involves crossing the pelvic limbs of the rod to insert them into the previously drilled pelvic holes (TECH FIG 3C).
- In patients with pelvic obliquity, the pelvic limb of the rod is placed into the drill hole on the low side of the pelvic obliquity first, with this side crossed underneath the other limb.
- With the rod impactor, the surgeon inserts half to three quarters of this pelvic limb of the rod first and then inserts the opposite pelvic limb, using a rod holder to direct it into the correct direction of the previously drilled hole.
- The rod impactor is next used to drive limbs into the pelvis, alternatively impacting each pelvic leg and making certain to direct each of the legs in the direction of the previously drilled holes.
- At this point, intraoperative fluoroscopy should be used to confirm the correct placement of the rod limbs within the pelvis.
- Caution: The surgeon should not try to see if the rod fits by pushing it down into the wound completely in one
move, as this may cause either the pelvic limbs of the rod to pull out of the pelvis or fracture of the ilium.
- The surgeon should push the rod to line up with the L5 lamina only and then twist the wires (we suggest a jet wire twister). The wires are cut 10 to 15 mm long.
- Now the rod is pushed to L4 and the wires are twisted and cut.
- Next the rod is pushed to L3 and the wires are twisted and cut.
- This process continues one level at a time until the surgeon reaches T1 (TECH FIG 3D).

### COMPLETION AND WOUND CLOSURE

- All wires are bent down into the midline of the rod and directly caudally. This allows easier exposure of the rod and wires if reoperation should ever become necessary.
- The remaining bone graft is applied (TECH FIG 4A).
- We mix the last 60 cc of allograft with four 80-mg vials of gentamicin. This has lessened the postoperative infection rate.
- If the child is thin and the sacrum is prominent, the sacral spinous processes and lateral processes are trimmed.
- The sacral lamina and lateral processes can be completely removed if they are severely prominent.
- The fascia is closed tightly.
- No drain is used.
- The subcutaneous tissue and skin are meticulously closed.
- Final radiographs are taken to confirm coronal and sagittal alignment (TECH FIG 4B–D).
- In patients with hyperlordosis, pedicle screws with reduction posts are useful in the apex of the sagittal plane deformity to aid in the correction (TECH FIG 4E,F).
Clinical photographs show correction of pelvic obliquity (C) and good sagittal plane alignment (D). Preoperative (E) and postoperative (F) lateral radiographs of patient with severe hyperlordosis corrected with unit instrumentation and pedicle screws used to correct lordosis in the apex of the deformity.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Severe intraoperative hypotension may suddenly occur, especially after decortication.</th>
<th>Constant communication between the surgeon and the anesthesiologist is critical. Type and cross-matched packed red blood cells (1.5 to 2 times blood volume), fresh-frozen plasma, and platelets should be available.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hypothermia</td>
<td>Hypothermia can be avoided by keeping the room temperature high and using a heated ventilator, a warmer for intravenous fluids and blood, and an airflow heating device.</td>
</tr>
<tr>
<td>Excessively stiff scoliosis or accompanying sagittal plane deformity (hyperkyphosis or hyperlordosis)</td>
<td>The surgeon should recognize stiffness preoperatively on the physical examination or bending radiographs to plan for anterior release.</td>
</tr>
<tr>
<td>Rod insertion</td>
<td>• Using the wires to pull the rod down to the lamina may cause the wires to cut through the lamina. • Relaxing the push on the rod between levels while correcting the major curve may cause an “unzipper” effect, with several wires tearing through laminae or breaking from too much force on the end vertebrae. • The surgeon should use a rod holder to prevent the pusher from slipping off the rod as the top of the rod is approached. • The force from pushing may become large, preventing the patient from being ventilated or causing a drop in blood pressure. If this occurs, the surgeon should relax the push on the rod just enough to allow ventilation and return of pressure.</td>
</tr>
<tr>
<td>Pelvic insertion of rod limb in severe lordosis</td>
<td>Difficulty occurs as the surgeon attempts to insert the pelvic limb of the rod and cannot get the rod anterior enough to steer the rod into the drill holes. This may allow the rod to perforate into the sciatic notch or through the inner pelvic table. • Intraoperative fluoroscopy should be used to check proper placement of the pelvic limbs. If pelvic penetration of the rod occurs, the penetrated rod limb should be cut, reinserted into the pelvis, and reconnected with an end-to-end or side-to-side connector.</td>
</tr>
<tr>
<td>Misjudgment of rod length</td>
<td>If the rod is too long and prominent, both rods can be cross-linked together and then cut at the T1 vertebrae. If the rod length is misjudged too short by more than two levels, the top of another unit rod can be connected with end-to-end connectors. This is important when there is excessive kyphosis to prevent drop-off of the spine over the top of the rod.</td>
</tr>
<tr>
<td>Wires cut through lamina</td>
<td>Only enough bone should be removed to allow wires to pass through the sublaminar space. Wires should not be used to pull the rod to the laminae. This may also be due to inadequate anterior release in a stiff deformity.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- Neuroromuscular patients are managed in the intensive care unit postoperatively.
  - Most children remain intubated and are ventilated over a 2- to 5-day period. This allows for easier respiratory management and pain management.
  - Core body temperature should be increased to 37°C and maintained. Blood clotting is impaired by low body temperature below 33°C, which can easily develop in this patient population.
  - Hypertensive episodes are avoided by maintaining increased fluid intake and pressor support as needed. Urine output should be maintained at a minimum of 0.5 cc/kg/hour.
  - Most children require aggressive postoperative nutritional support with central hyperalimentation.
    - Typically, a tunneled central venous catheter (Hickman) is placed at the time of surgery.
    - Gastrostomy tube feedings can be started as soon as bowel sounds are present.
    - Gastrojejunostomy or nasojejunostomy tubes may be started as an alternative to hyperalimentation.
  - Pancreatic enzyme levels are monitored carefully postoperatively, as elevated amylase and lipase levels are common and indicative of subclinical pancreatitis.
  - Oral or gastrostomy feedings should be delayed if these values are increasing above normal.
  - Adequate nutritional intake for optimal wound healing usually requires about 1.5 times the child’s normal preoperative requirements and is continued up to 1 month postoperatively.
  - Proper wheelchair assessment postoperatively is also important.

OUTCOMES

- Unit rod instrumentation achieves a scoliosis correction of 70% to 80% of the preoperative curve magnitude and an 80% to 90% correction of pelvic obliquity.4
  - In a subset of 24 ambulatory cerebral palsy patients who underwent posterior spinal fusion with unit rod instrumentation, all patients had preservation of their ambulatory status.20
  - Sagittal plane spinal deformity is also well corrected with unit rod instrumentation. Lipton et al8 showed relief of symptoms and correction of sagittal plane spinal deformity in 24 cerebral palsy patients with hyperlordosis and kyphosis after unit rod instrumentation.
  - In one survey of 190 parents and caretakers assessing functional improvement of children with cerebral palsy after posterior spinal fusion, 95.8% of parents and 84.3% of caretakers would recommend spinal surgery again.18 Positive responses included improved appearance, overall function, quality of life, and ease of care.
  - Overall life expectancy of the cerebral palsy child after posterior spinal fusion is also critically important. A survival analysis showed that the presence of severe preoperative thoracic hyperkyphosis and the number of postoperative days in the intensive care unit correlated with decreased life expectancy after evaluating a number of variables.19

COMPLICATIONS

- Complications are common but are usually not life-threatening and range from minor to major. They include excessive intraoperative bleeding, neurologic complications, atelectasis, pneumonia, prolonged postoperative ileus, pancreatitis, wound infection, and so forth.
  - Mechanical or technical complications also occur and include rod or wire prominence, pseudarthrosis, rod penetration through the pelvis, curve progression after fusion due to crankshifting, and so forth.
  - In one study, the curve magnitude, preoperative pulmonary status, and degree of neurologic involvement had the highest correlation with postoperative complications.9

REFERENCES

Early-onset scoliosis (EOS) is defined by the diagnosis of scoliosis at or before the age of 5 years. The many etiologies of EOS include:

- Congenital vertebral or spinal anomalies: eg, vertebral bars, hemivertebrae, syrinx, tethered cord
- Neuromuscular diseases: eg, cerebral palsy, spinal dysraphism, muscular dystrophy
- Syndromes associated with scoliosis: eg, neurofibromatosis
- Idiopathic causes

Age of onset is an important aspect of pathology, because progressive curves can be associated with growth disturbances as well as cardiopulmonary compromise, including restrictive lung disease and pulmonary hypertension.

Two periods of increased growth velocity are associated with increased incidence of curve progression. The first occurs from birth to 5 years of age; the second includes the adolescent growth spurt occurring after age 10 until just before skeletal maturity.

The growth velocity from T1 to L5 is greatest from birth until the age of 5. Increases in height during this period average 2 cm per year, and by the age of 5, two thirds of the final sitting height is achieved. The years between 5 and 10 years of age exhibit much less growth. Finally, the adolescent growth spurt causes another increase in growth velocity, at a slower rate than the first growth spurt.

The increased spinal growth during the first years of life is paralleled by an increase in thorax and lung dimension. Thoracic volume at birth is about 5% of the adult volume; by 5 years of age, it equals 30% of adult volume. A slower rate of thoracic growth occurs from 5 to 10 years of age, by which time it has reached 50% of the adult volume. The final 50% of adult volume is achieved during the adolescent growth spurt from 10 to 15 years of age.

Lung development also occurs rapidly during the first year of life, and by age 8, most alveolar growth and respiratory branching has occurred.

The pathogenesis of EOS depends on its etiology. Vertebral anomalies cause scoliosis by an imbalance in bone growth, whether an increase on a side associated with a hemivertebrae, or retardation on the side associated with a vertebral bar. In neuromuscular and central nervous disorders, an imbalance in muscular forces is the pathogenesis, likely following the Heuter-Volkmann principle.

The etiology and pathogenesis of infantile idiopathic scoliosis (IIS) (0–3 years of age) is, by definition, unknown. There probably is a genetic component that provides a susceptibility to develop scoliosis. The external factors needed to produce the scoliosis are not yet clearly delineated but may include intrauterine molding as well as infant positioning. The etiology of IIS most likely differs from that of adolescent idiopathic scoliosis (AIS).

The natural history also depends on the etiology. The natural history of EOS due to IIS is favorable when compared with late-onset scoliosis (LOS). Spontaneous resolution occurs in a large number of patients. Progression of congenital curves depends on the type of anomaly and growth potential. EOS due to neuromuscular etiologies usually follows the natural history of the disease in addition to specific problems associated with progressive curves in this age group.

Regardless of the etiology, progression of scoliosis during the first 5 years of life adversely affects growth as well as pulmonary function. Scoliosis inhibits the growth of both the alveoli and the pulmonary arterioles, causing ventilation defects. The scoliotic spine does not distort the architecture of the alveoli; rather, the total number is decreased significantly and is directly proportional to the age of onset. The earlier the onset of scoliosis, the more hypoplastic the lung is, with a diminution of alveoli greater than would be expected from just a lack of space.

Patients with EOS also may suffer from a restrictive pattern of pulmonary dysfunction. Lung compliance is reduced, with an associated decrease in total lung capacity as well as vital capacity. In contrast to patients with LOS, the severity of scoliosis in EOS is proportional to the severity of restrictive disease. The restrictive lung disease causes hypoventilation and vasoconstriction of the pulmonary tree and leads to pulmonary hypertension. EOS is associated with a higher risk of cardiopulmonary decompensation in middle-aged patients, which can lead to disabling and even fatal respiratory failure.

Evaluation of the patient with EOS includes a complete history, including the family history, prenatal history, birth history, and developmental history. IIS has been associated with breech presentation and, in boys, with premature birth. Curve progression also has been correlated with cognitive delay, so it is important to ask parents about the achievement of developmental milestones.

The physical examination of EOS heavily relies on the perceptive capabilities of the clinician and is the same examination that is performed on all scoliosis patients. After a careful history has already been obtained, a thorough physical examination, including inspection, palpation, motor testing, sensory testing, and reflex testing is necessary.

Inspection includes observation of gait, respiration, truncal and pelvic balance in the coronal and sagittal planes, cutaneous lesions, and any prominence on forward bending. Any deficits in
motor, sensory, or reflex function, including abdominal reflexes, may indicate central nervous system pathology and should be thoroughly evaluated with advanced diagnostic studies.

- Flexibility of the curve can be assessed either by the manual application of traction through the cervical spine or by applying a three-point bending force at the apex of the curve. Examination techniques unique for early-onset scoliosis include the thumb excursion test for thoracic expansion and sitting height measurement.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- All patients should have full-length standing anteroposterior (AP) and lateral radiographs (**FIG 1A,B**) covering the cervical spine to the pelvis, including the entire thorax. For patients who are unable to stand, supine radiographs encompassing the same area should be taken.
- The cervical spine, lumbosacral spine, pelvis, and hips all may need to be studied to elicit whether or not developmental hip dysplasia or other vertebral anomalies are contributing to the scoliosis.
- Side-bending or traction radiographs are necessary to help delineate the degree of flexibility of the curves.
- Similar to LOS evaluation, the Cobb technique is used to measure any curve by measuring the angle created by a line through the superior endplate of the most cranial vertebra and a line through the inferiormost point of the most caudal endplate. This should be done in both the coronal and sagittal planes and compared to normal values. These angles can be used to measure progression of the curve with successive visits but are subject to a small amount of user error variability between 5 to 6 degrees.
- Spinal height is obtained by measuring the distance from the top of T1 to the top of S1 on the AP view of the spine (**FIG 1C**). 
- Coronal balance is measured by the distance from the center of C7 to a line drawn up from S1.
- The sagittal balance is measured from the posterior-cranial corner of S1 to a line drawn down from the center of C7.
- All of these measurements should be recorded and compared on successive visits to document any change in curve magnitude or growth of the spine.

- The rib-vertebral angle difference of Mehta (RVAD; **FIG 2**), first described in 1972, measures the amount of rotation at the apex vertebra and has some prognostic value. The angles formed by a line perpendicular to the vertebra and a line drawn down the center of the rib is compared between the convex and concave side. If the difference calculated by subtracting the convex angle to the concave angle is 20 degrees or less, there is an 85% to 90% chance the curve will resolve; when there is a difference of 21 degrees or more it will likely progress.

- The phase of the rib head also is described by ascertaining whether the head of the convex rib overlaps the vertebral body. 
- If there is no overlap (phase 1), then the RVAD is calculated as previously mentioned.
- If there is overlap (phase 2), the risk of progression is high, regardless of RVAD.
- Another method of evaluating rotation is the Nash-Moe method (**FIG 3**). Evaluating the pedicles of the apical vertebra at the convexity, the distance of the pedicle on the convex side is measured.
  - Zero: the pedicles are equidistant from the sides
  - Grade 1: the concave pedicle is partially obscured, and the convex pedicle moves away from the edge toward the center
  - Grade 3: the convex pedicle is in the midline of the vertebral body.
  - Grade 2: between grades 1 and 3
  - Grade 4: the convex pedicle lies past the midline.

**FIG 1** • **A.** Lateral radiograph of a neuromuscular patient with early-onset scoliosis. **B.** AP radiograph with space available for the lung (SAL) of a patient with early-onset scoliosis. **C.** Measurement of vertebral height from T1 to S1.
Differential Diagnosis

- Congenital vertebral or spinal anomalies
  - Vertebral bars
  - Hemivertebrae
  - Syrinx
  - Tethered cord

FIG 2 • The rib-vertebral angle difference (RVAD) measures the angle of a line drawn perpendicular to the apical thoracic vertebra endplate and a line drawn down the center of the concave and convex ribs. The difference is calculated by subtracting the convex from the concave angle. An RVAD of 20 degrees or less indicates a curve that is likely to resolve; an RVAD of 21 degrees or greater often is associated with curves that will progress. The phase of the rib head notes the position of the convex rib head on the apical vertebra. A “phase 1” relationship indicates no overlap of the rib head or neck on the apical vertebra. In cases that have a phase 1 relationship, the RVAD may be calculated and used to determine the likelihood of progression. In a phase 2 relationship, the head of the rib on the convex side of the apical vertebra overlaps with the vertebra, and the curve is likely to progress. (Adapted from Mehta MH. The rib-vertebra angle in the early diagnosis between resolving and progressive infantile scoliosis. J Bone Joint Surg Br 1972;54B:230–243.)

FIG 3 • Measurements performed on apical vertebra. If the pedicles are equidistant from the sides, rotation is classified as zero. If the concave pedicle is partially obscured and the convex pedicle moves away from the edge toward the center, that is considered grade 1. Grade 3 is defined as the convex pedicle in the midline of the vertebral body. Grade 2 lies between grades 1 and 3. Grade 4 indicates that the convex pedicle lies past midline. (Adapted from Nash CL Jr, Moe JH. A study of vertebral rotation. J Bone Joint Surg Am 1969;51A:223–229.)

FIG 4 • CT scan of the chest showing decreased lung volumes due to scoliosis.
Chapter 62  GROWING ROD INSTRUMENTATION FOR EARLY-ONSET SCOLIOSIS

NONOPERATIVE MANAGEMENT

Nonoperative treatment for EOS is indicated in curves that are not expected to progress or that are expected to progress only mildly, taking into consideration the etiology of the curve and the radiographic parameters described by Mehta in cases with IIS.

- Patients with a curve less than 25 degrees and RVAD less than 20 degrees may be followed with serial radiographs every 4 to 6 months to document any progression.
- Active treatment is warranted in:
  - Progression greater than 10 degrees; treatment starts with casting and bracing.
  - Phase 2 rib-vertebral relationship, RVAD greater than 20 degrees, or a Cobb angle greater than 20 degrees in any skeletally immature patient
  - Progression of more than 5 degrees in a patient with a Cobb angle greater than 35 degrees
- Casting usually is done under anesthesia. The cast is changed every 6 to 12 weeks until the ultimate correction is achieved.
- After casting, a Milwaukee brace (FIG 5) is used for 23 hours a day to help maintain the correction. Fully circumferential braces may distort the rib cage and adversely affect pulmonary status, because the immature thoracic wall may deform before any correction of the spine occurs.
- Bracing is continued for a minimum of 2 years until the Cobb angle and RVAD are stable.
- The goal is to correct the deformity completely before the prepubertal growth spurt.

- Nonoperative treatment for neuromuscular or congenital scoliosis can be attempted for curves of lesser magnitudes. Treatment options available include casting and bracing.
- Bracing is less effective for these types of deformities than for idiopathic scoliosis, but can be used in long flexible curves.
- Deformities with large sagittal components are not amenable to brace treatment.
- Brace treatment for congenital or neuromuscular scoliosis should be abandoned when unacceptable curve magnitude or progression is seen.

SURGICAL MANAGEMENT

Surgical treatment of EOS attempts to stop progression of the scoliosis, allowing improvements in growth of the spine, thorax, and lungs.

- Surgery is recommended for progressive curves greater than 45 degrees.
- The age of the patient helps to decide the type of surgery needed.
- Adolescents and more skeletally mature patients may do well with spine fusions, which stabilize the spine but also stop growth.
- Younger patients with substantial growth potential suffer from the “crankshaft” phenomenon if fusion is performed early in life from an isolated posterior approach. They suffer from severe growth retardation in height and thorax volume if fusion is performed using a combined anterior and posterior technique.
- The growing rod technique for EOS was developed to correct spinal deformity while allowing spinal growth to continue or even enhancing that growth.

Preoperative Planning

- Careful evaluation of radiographic studies allows planning of surgical levels. Typically, the cranial level of the construct includes T2 and extends two or three levels caudal to the end vertebra of the curve.
- Either pedicle screws or hooks can be used in the construct. Review of the pedicle structure using radiographs and CT scans is necessary to be sure the desired implants are selected.
- Medical and subspecialty consultations should be obtained before operation if the patient has any history of medical comorbidities.
- Cardiopulmonary, renal, skeletal, and other neuromuscular defects often are associated with scoliosis.
- Pulmonary function tests may be obtained in children who are able to cooperate if thoracic insufficiency is suspected.

Positioning

- The patient is placed under general anesthesia on the stretcher and then placed on the operating room table in the prone position on two longitudinal chest rolls or tightly rolled blankets.
- Neural monitoring is used during the procedure for neurologically intact patients. Leads should be placed before prone positioning, as should a Foley catheter.
- Care must be taken to be sure all bony prominences and compressible nerves are well padded.

Approach

- The growing rod technique is performed posteriorly through either a single long midline incision or two smaller incisions cranially and caudally.
**GROWING ROD INSTRUMENTATION FOR EARLY-ONSET SCOLIOSIS**

**Single-Incision Technique**

**Exposing the Foundations**
- The single-incision technique consists of a long superficial posterior incision beginning 2 to 3 cm cranial to the planned levels and ending caudal to the lowest vertebra by 2 to 3 cm. Infiltration of epinephrine may be used before subcutaneous incision.
- The spinous processes of the cranial and caudal foundations are exposed and marked with a metallic object such as a Kocher clamp, and a lateral radiograph is then used to confirm the levels.
- The foundations are critical to the construct in the dual growing rod technique.
  - They are composed of at least two pair of anchors and usually span two or three vertebral levels.
  - The foundations consist of the vertebral segments at either ends of the constructs, which are internally fixed with anchors.
  - Because the corrective loads are applied to these foundations, it is imperative that strong and stable constructs be achieved to decrease the incidence of implant or fixation failure.
- Limited fusions of the foundation levels often are performed using local bone graft or allograft extenders to provide more stability.
- The posterior elements of the cranial and caudal foundations are exposed subperiosteally out to the level of the transverse processes.
- Vertebral levels not involved in a foundation should not be exposed, to decrease the chance of unwanted fusion.

**Placing the Anchors**
- Once exposure has been obtained, the anchors are placed.
- The foundations may be anchored using either pedicle screws or hooks.
- If hooks are used, the superior edges of the most cranial lamina or transverse processes (TP) on either side are exposed, and supralaminar hooks or TP hooks are placed in a downdragging manner on both sides.
- Contralateral supralaminar hooks may be staggered over two levels if canal stenosis is a concern.
- Next, upgoing hooks are placed, usually under the facet articulations of the same vertebra but sometimes in a staggered arrangement.
- Foundations using supralaminar hooks generally consist of three vertebral levels with supralaminar hooks placed on either side of the cranial two vertebra and the facet hooks placed on the most caudal one.
- If TP hooks are used, only two vertebral levels are used, with the TP hooks placed on either side of the cranial vertebra and the facet hooks placed on the same cranial vertebra.
- For more stability, additional facet hooks can be used to extend the foundation to three levels. It is important to achieve adequate stability at initial surgery.
- Pedicle screws also may be used, usually with four screws spanning two vertebral levels. Pedicle screws may offer increased stability to the construct and are preferred for both foundations as long as the anatomy allows their safe placement.
- Multiple methods for thoracic pedicle screw placement have been popularized. In general, the thoracic pedicle starting point is located at the intersection of the lateral border of the superior articular facet and the cranial aspect of the transverse process.
- The trajectory of the thoracic pedicle screw generally travels lateral to medial about 30 degrees and from cranial to caudal 10 degrees, but varies by level (TECH FIG 1A–C).
- Lumbar pedicle screws start at the junction of the pars interarticularis, the midpoint of the transverse process, and the base of the superior articular process.
- Lumbar screw trajectory also varies, from about 10 degrees at L1 to 30 degrees at L5 from lateral to medial, and varies in the sagittal direction approximately 10 degrees from L1 to L5, depending on lordosis (TECH FIG 1D).
- Fluoroscopy and neural monitoring are helpful in aiding pedicle screw placement, especially in patients with deformity. If needed, a combination of hooks and screws can be used.

**Adding the Rods**
- The dual rod technique employs two rods, each made up of a cranial foundation rod and a caudal foundation rod joined by a connector, for a total of four rods for the entire construct.
- Either of two types of connectors may be used: a tandem connector, which houses the cranial and caudal rods inside a rectangular box so the ends meet end to end, or side-to-side connectors, which allow the rods to overlap.
- Tandem connectors usually are favored. Because they are straight and cannot be contoured, the rods are measured so that they meet inside the tandem connector in the relatively straight thoracolumbar region.
- The ends of the rods that fit inside the connector also must be straight. If any contouring is necessary in the region where the cranial and caudal rods meet, closed dual connectors must be used, with an overlap of 2 to 4 inches to allow future lengthening.
- Bilateral rods are prepared for each foundation by measuring the length of the spine in the corrected position and carefully contouring the rod. The concave side usually is constructed first to gain maximal correction.
- The rods can be placed either subcutaneously or subfascially. Subfascial placement involves a much deeper dissection, both initially and with each lengthening, however, and may increase the risk of premature fusion. Subcutaneous placement may be associated with a higher incidence of skin problems and wound infection.
After the rods are placed in the hooks or screws of each foundation, transverse connectors are placed between the two cranial rods and the two caudal rods, preferably between the points of fixation on each foundation.

If the transverse connectors are close-holed, it may be necessary to preload them onto the rods before they are placed in the anchors, and the spinous processes may be removed to allow proper seating.

These transverse connectors increase the stability of the construct, especially when hooks have been used. There is less need for transverse connectors when screws are used.

The tandem connector is held with a rod holder and slid onto the cranial rod; once the caudal rod is cleared, it is slid onto the caudal rod.

The cranial anchors and transverse connector are tightened first, followed by the caudal anchors and transverse connectors. Cranial and caudal set screws are located on the side of the tandem connector that correlates to the most prominent side.

To create distraction, the caudal set screw is tightened, a distractor is implemented in the slot of the tandem connector between the two rods, and the cranial set screw is tightened (TECH FIG 2A).

Similarly, a rod clamp can be used to distract against if a closed dual connector is used or even on a tandem connector (TECH FIG 2B).

Next, the rod construct on the convex side of the curve is created similarly and tightened. The surgical area is then irrigated, followed by a limited arthrodesis applying autograft bone or other graft extenders between the vertebrae making up each foundation.

Before final closure, anteroposterior and lateral radiographs are taken to confirm alignment and proper position of the implants (TECH FIG 2C,D).

The wound is then closed in standard fashion.

**Dual-Incision Technique**

The dual-incision technique differs from the single-incision technique in a few ways.

The incisions are centered over the foundation sites with a long skin bridge between them (TECH FIG 3).

The subperiosteal dissection is the same, as are placement strategies of either hooks or pedicle screws for anchors.

In placing the rods, however, subcutaneous or subfascial dissection must be performed carefully and bluntly with either a finger or blunt clamp to facilitate rod passage.

Careless dissection or poor control of the rod during passage can lead to pleural violation.

The rods must be placed beneath the skin bridge and the tandem connector placed on the caudal rod before they are fitted into the anchors.

The rest of the procedure is similar to the single-incision technique.

**Lengthening and Exchange**

Lengthening of the dual rod construct may be performed as either an in- or outpatient procedure with neural monitoring for patients with normal neurologic function.

The connector is located through palpation or fluoroscopy, and a small incision is made over that area where the lengthening is planned.
TECH FIG 2 • A. Lengthening may be performed by inserting the distractor between the rods through the slot of the tandem connector. One set screw is loosened, distraction is performed, and the set screw secured. B. Alternatively, a rod clamp can be placed on the rod a few centimeters from the connector and the distractor placed between the rod clamp and the end of the connector. The set screw nearest the rod clamp is then loosened, the distractor employed, and the screw retightened. C. AP radiograph after the dual growing rod procedure was performed on the patient shown in Figure 1B and C. D. Lateral radiograph after the dual growing rod procedure was performed on the same patient. (A,B: Bagheri R, Akbarnia BA. Pediatric Isola instrumentation. In: Kim DH, Vaccaro AR, Fessler RG, eds. Spinal Instrumentation: Surgical Techniques. New York: Thieme, 2005:640,642.)

- After dissection of the connector is performed, lengthening similar to that performed during the index procedure is carried out by loosening the set screw (mostly cranial), distracting between the two rods, and then tightening the set screw again.
- Lengthening is performed every 6 months.
- Once further distraction is no longer achievable, final correction and arthrodesis are performed.

Changing the Connector or Rod
- Exchange of the tandem connector or the rod may be needed if the amount of lengthening exceeds the initial length of the tandem connector.

- In such a case, both set screws should be loosened and the tandem connector slid cephalad until full clearance of the caudal rod is achieved.
- The connector can then be removed off the cranial rod, replaced by a longer connector, and slid onto the caudal rod again.
- Longer than 70 mm connector is rarely used, to minimize the adverse effect on sagittal balance.
- If the needed length exceeds the longest connector or if the longest connector is too long, it is necessary to fashion new rods and remove the old ones.
- This entails exposing and removing the tandem connectors, exposing the foundation, and removing the rods and replacing them with longer rods, creating a construct similar to the initial procedure.
- Replacement of the cephalad rods is most common.

Final Fusion
- Final fusion is performed near the end of the adolescent growth spurt or when the rods can no longer be lengthened.
- The first step entails removing the dual growing rod implants, including the anchors and exploring foundations for solid fusions. One should be careful to cause the least trauma to the soft tissues.
- For most patients, the fusion should extend from the cranial foundation to the cephalad foundation.
Either hooks or pedicle screws can be used in the foundations and at the apices of the curves. Rods are then contoured to the desired shape, keeping in mind that the goal is to achieve global balance rather than a totally straight spinal segment. Thus, upper and lower curves should be considered together when contouring the rods.

A consideration when performing the final fusion is that posterior osteotomies may be required, especially if a subfascial technique is employed, because the posterior elements may become stiff after repeated exposures. This usually can be done safely by finding the neural canal and then osteotomizing the pars on either side.

Another consideration is that the areas around the anchor sites often are overgrown with bone, and taking the implants out often entails osteotomizing the bone around the anchors. Care should be taken to point away from the spinal canal to avoid neural injury. Although pedicle screws offer three-column support in the foundations, replacing hooks in the fusion mass provides sufficient strength if placed properly, and hooks are easier to place, especially if they were used initially for the growing rods.

Sublaminar wires also offer an attractive option and are useful if lateral translation of the spine is required.

### Pearls and Pitfalls

<table>
<thead>
<tr>
<th>Exposure</th>
<th>Avoid subperiosteal dissection anywhere except the foundation to avoid premature fusion. Use careful blunt dissection beneath the skin bridge to avoid pleural violation.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Implants</td>
<td>Perform a careful radiographic examination if pedicle screws are desired. Use proper rod contouring to correct both coronal and sagittal deformity. Tandem connectors are straight and should be placed at the thoracolumbar region, which also is straight.</td>
</tr>
<tr>
<td>Lengthening</td>
<td>Do not be too aggressive with lengthenings, especially at the index procedure and first lengthening, to avoid implant issues.</td>
</tr>
<tr>
<td>Indications</td>
<td>May not be indicated in very stiff curves, poor bone quality, older children with limited growth potential, or children too young to allow internal fixation.</td>
</tr>
</tbody>
</table>

### Postoperative Care

Patients are braced postoperatively with a thoracolumbosacral orthosis, beginning when they have been upright for up to 6 months and continuing until fusion of the foundations. Rehabilitation proceeds according to the patient’s tolerance and ability.

### Outcomes

Documented outcomes are short-term, and no level I studies are currently available.

One study showed Cobb angle correction from an average of 82 degrees to 36 degrees at last visit or final fusion.

Spine growth is almost equal to normal, averaging 1.21 cm/year.

Some patients averaged almost 12 cm of growth.

SAL increased from 0.87 to 1.

Better balance and cosmesis

### Complications

- Wound breakdown
- Infection
- Junctional kyphosis
- Crankshaft phenomenon
- Curve progression
- Implant failure

Patients with more frequent lengthenings have fewer implant problems but more wound problems, whereas patients with less frequent lengthenings have more implant problems and fewer wound complications. Implant complications often can be treated during scheduled lengthenings, but wound infections should be treated urgently.

### References

DEFINITION
- A hemivertebra is a congenital anomaly of the spine that forms during the 8th to 12th weeks of embryologic development. It is characterized by the formation of half of a vertebral body, a corresponding pedicle, and a corresponding hemilamina.
- Hemivertebra are classified as a congenital failure of formation.
- A hemivertebra may be classified as fully segmented (ie, separated from the bodies above and below by discs); partially segmented (ie, separated from one adjacent body by a disc and fused to the other adjacent body); or unsegmented (ie, fused to the body above and below; FIG 1).3
- Progressive curvatures of the spine caused by a hemivertebra result from unbalanced growth. Full-segmented hemivertebra have a much higher rate of progression, because the presence of an intact disc space above and below signifies the presence of growth plates and potential asymmetrical spinal growth.

ANATOMY
- The hemivertebra has a partial vertebral body, a pedicle, and a hemilamina.
- Anatomically, it may be joined to the level above or below at either the body, the hemilamina, or both. If the hemivertebra is not fused to either adjacent segment, the potential for asymmetric spinal growth is high.
- A local kyphotic or lordotic deformity may occur with hemivertebra if the associated failure of formation is greater anteriorly or posteriorly.

PATHOGENESIS
- Progressive spinal curvatures due to hemivertebra are a result of disordered growth.
- The hemivertebra is a wedge on the convex side of a curve. In the presence of healthy growth plates above and below (ie, a fully segmented hemivertebra) convex growth is faster than contralateral concave growth, causing a progressive scoliosis.
- In cases of hemivertebra, if the vertebral body lies in the posterolateral quadrant, a progressive kyphosis may arise with the scoliosis.
- The disordered growth eventually may cause curvature to such a degree that normally segmented areas of the spine become involved in the curve, causing deformity and spinal imbalance.

NATURAL HISTORY
- The natural history of a hemivertebra depends on its location and the potential for growth and curve progression.
- Hemivertebrae that are fully segmented progress at approximately 2 degrees a year and can exceed over 45 degrees at maturity.5 These require treatment to prevent deformity and also to prevent adjacent spinal curvature.
- Partially segmented hemivertebrae have much less growth potential (less than 1 degree per year), rarely exceeding 40 degrees at maturity. They usually do not require treatment. Unsegmented hemivertebrae require no treatment.
- Hemivertebra at the lumbosacral junction almost always require treatment, because the lumbar spine takes off obliquely from the sacrum, causing a long compensatory curve in normally segmented regions of the lumbar spine, with resultant cosmetic deformity and spinal imbalance.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Embryologic development of the spine occurs between the 8th and 12th weeks of gestation; hence, other organ systems developing at the same time also may have a congenital anomaly.
- A complete musculoskeletal examination looking for diagnoses such as clubfoot, developmental dysplasia of the hip, and limb anomalies is warranted.
- A complete neurologic examination should be performed, because as many as 40% of patients with congenital scoliosis have a corresponding spinal dysraphism. This examination includes sensory, motor, and reflex testing.
- Occult signs of spinal dysraphism include cutaneous manifestations such as midline spinal hemangiomas, penetrating sacral dimples, or midline hairy patches. Foot anomalies such as vertical talus or asymmetric cavus feet can signify spinal dysraphism.
- Cardiac auscultation should be done, because 20% of patients with congenital scoliosis have congenital heart anomalies.
- Observe shoulder position, trunk position, and waist symmetry. Truncal imbalance is an indicator of curvature.
- Observe the flexibility of the patient’s spine.
- Rotation of the spine during the Adams forward bend test is indicative of deformity and points to its location.
IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standing 36-inch posteroanterior (PA) and lateral radiographs are mandatory to define the deformity and assess the Cobb measurement. Apparent progression may be seen from supine radiographs to standing radiographs (FIG 2A).
- Bending radiographs, in which the patient is directed to bend in a concave and then in a convex direction, are necessary to assess the flexibility of curves above and below the hemivertebra.
- MRI scanning of the brainstem and spinal cord is mandatory before any surgical intervention, given the height rate (30% to 40%) of congenital scoliosis with spinal dysraphism.\(^3\)
- CT scans with three-dimensional (3D) reconstructions should be obtained to delineate the anatomy of the anterior and posterior elements as an aid in planning the operation and to avoid intraoperative problems such as unexpected posterior element deficiencies or fusions (FIG 2B).\(^4\)
- A pediatric protocol should be used for CT scans to avoid the significant radiation exposure that results when adult protocols are used for children.
- Preoperative evaluation of the genitourinary system with a screening ultrasound and evaluation of the cardiac system with an echocardiogram are necessary if these have not been performed, given the rate of anomalies associated with congenital scoliosis.

DIFFERENTIAL DIAGNOSIS
- Failure of vertebral formation
- Failure of vertebral segmentation
- Sequela of infection causing partial vertebral body destruction
- Tumor

NONOPERATIVE MANAGEMENT
- Nonoperative management is reserved for nonprogressive curves caused by hemivertebra.
- Hemivertebra associated with little or no curve progression (unsegmented or partially segmented) may be followed during growth with radiographs every 6 to 12 months, depending on the degree of deformity and age of the basis.
- Bracing has no role in the management of a hemivertebra.

SURGICAL MANAGEMENT
- The classic indication for a hemivertebra resection is a patient with a progressive curve secondary to a fully segmented hemivertebra in the thoracolumbar, lumbar, or lumbosacral regions with a resultant deformity.
- We have found that excision is best performed between the ages of 18 months and 4 years.
- Patients younger than this may be more difficult to instrument, and waiting until this age rarely has caused irrevocable deformity.
- Excision in older patients is feasible; we have found, however, that if diagnosed early there is no reason to wait past the age of 4 years given the progression of curvature and its effect on normally segmented regions of the spine.
- Instrumentation at these ages is technically feasible.

Preoperative Planning
- Review of the preoperative MRI of the spine
  - If spinal dysraphism is present, referral to a neurosurgeon is mandatory.
  - If the patient requires neurosurgical intervention for dysraphism, that procedure should precede the hemivertebra excision, either at the same setting or in a staged setting, at the discretion of the spine surgeon and neurosurgeon.
- Review of the 3D CT scans
  - A complete understanding of the anatomy of the hemivertebra is crucial to avoid intraoperative confusion, especially because associated posterior element fusions or absences can make identifying levels difficult.
  - Studying the pedicle anatomy (ie, length and diameter) of the levels above and below is efficacious given the smaller size of these patients.
- Neurologic monitoring is important and should be done using somatosensory evoked potentials and motor evoked potentials.
- Communication between the monitoring and anesthesia teams should be facilitated to prevent any change in neurologic function brought on by anesthetics, hypotension, or low blood volume.

Positioning
- We perform hemivertebra excisions with the patient in the prone position.
  - This is done on a radiolucent operating frame with chest and pelvic support, which leaves the abdomen free.
  - We also have found it useful to slightly “airplane” the table or bolster the patient so that the convex side is slightly higher than the concave side. This helps with visualization anteriorly, control of bleeding, and retraction of the dura and its contents (FIG 3).
- Before draping the patient, we place a marker over the hemivertebra region and obtain a radiograph.
  - This both confirms the side of the hemivertebra and helps limit excessive incisions and dissections.
- In the past we recommended that hemivertebra excision be performed as a simultaneous anterior-posterior procedure.\(^4\)
  - If the surgeon elects to do this, the patient is placed in the lateral decubitus position with the anterior and posterior fields being prepped into the fields. The patient should be

FIG 2 • A. Standing PA radiograph of a 5-year-old patient with a fully segmented hemivertebra at the thoracolumbar junction. B. A three-dimensional reconstructed CT scan of a fully segmented hemivertebra in a different patient.
placed at the edge of the bed to facilitate retractor placement in the posterior field.
- The anterior approach is on the convex side and should be marked before the patient goes to the operating room.
- We still recommend considering an anterior–posterior procedure when medical conditions (eg, congenital heart disease) caution against excessive bleeding, when a lordotic component renders access to the vertebral body difficult, and when the surgeon is unfamiliar with posterior-only approaches to circumferential surgery.

**Approach**
- If an anterior–posterior procedure is being performed, the anterior procedure should be a standard transthoracic, transthoracic-retroperitoneal, or retroperitoneal approach, depending on the location of the hemivertebra. The anterior approach often can be a limited one, because the only exposure needed is of the hemivertebra and the discs above and below.
- The posterior approach is a standard posterior midline incision with subperiosteal dissection out to the tips of the transverse processes.
- Diathermy aids in keeping blood loss to a minimum during dissection.
- Preoperative review of the CT scan should forewarn the surgeon of posterior element fusions and, more importantly, posterior element deficiencies.
- Dissection should proceed with caution over areas of laminar deficiency.
- Once completely dissected, a spot radiograph or fluoroscopic view should be obtained to confirm the appropriate level.

**HEMIVERTEBRA EXCISION**

**Pedicle Screw Placement**
- Implant anchors should be placed before excision, because blood loss at this point should be at a minimum.
- Where possible, we prefer bilateral pedicle screws as a basis for fixation. Pedicle screws may be placed in patients as young as 1 year of age.
- Preoperative CT scans can help assess the feasibility of screw placement.
- Implants should be titanium, and either 3.5- or 4.5-mm rod systems should be used in younger patients.
- Screw diameter and length can be at least estimated based on the preoperative CT scan.
- Screws should be placed in a stepwise manner, beginning with obtaining a cancellous blush with a burr at the appropriate starting position.
- Starting positions in normally segmented areas of the spine are well documented.
- A pedicle awl can then be used to obtain access down the pedicle into the vertebral body.
- Once the pedicle has been accessed, probing of the four walls of the pedicle and floor of the body is necessary to confirm accurate position. We then use the probe as a depth gauge to determine screw length.
- The hole is then tapped 0.5 mm under the expected screw diameter, and the pedicle walls and floor are reprobed.
- A fixed-angle screw of the appropriate diameter and length is then placed (TECH FIG 1A).
- Appropriate screw position is confirmed using triggered EMG stimulation of all screws (TECH FIG 1B) and then checking PA and lateral radiographs and fluoroscopic views (TECH FIG 1C).
Hemivertebra Excision

- The first step in excision is dissecting over the edge of the transverse process and down the lateral wall of the body using a Cobb elevator and curved-tip device, followed by curved retractor placement (TECH FIG 2A).
  - This step aids in protection of structures lateral and anterior to the wall on the hemivertebra. If the hemivertebra is in the thoracic region, it will be necessary to resect the rib head first to obtain access.

- The cartilaginous surfaces of the concave facet should be resected to encourage fusion.

- Resection then begins in the midline with the ligamentum flavum using a Kerrison rongeur (TECH FIG 2B,C), followed by resection of the hemilamina.
  - Resection should extend over to the facet, while the exiting nerve roots above and below the hemivertebra are identified and protected.
  - The transverse process and dorsal cortical bone over the pedicle can be resected in similar fashion until the cancellous bone of the pedicle and cortical outlines of its wall are visualized (TECH FIG 2D,E).
  - Care should be taken to avoid nerve roots, which are present rostral and caudal to the pedicle walls of the hemivertebra.
  - Gelfoam (Pfizer Inc, New York, NY) and cottonoids should be used judiciously to protect the dura and create a space between dura and bone to be resected.
  - The subperiosteal plane down the lateral wall of the pedicle and body is then developed, with a Cobb elevator used to facilitate retraction and protection. The dural contents can be protected by a nerve root retractor.
  - Bipolar sealing of epidural vessels that lie on the medial aspect of the pedicle and down on the inner wall of the body will aid in controlling blood loss and improving visualization.

- Continued resection down the pedicle and into the hemivertebra body can be done by a diamond-tipped burr, which helps protect against unwanted injury to soft tissue structures.

- Working stepwise within the walls of the pedicle and down within the confines of the body helps protect surrounding vital structures and makes removal of the cortical shells easier (TECH FIG 2F). The walls of the pedicle can then be easily resected with a curette or pituitary rongeur, as can the remaining walls of the body of the hemivertebra.

- Protection lateral and anterior to the confines of the hemivertebra wall is necessary to avoid injury to vital structures such as the aorta. Generally, the dorsal cortex of the vertebral body is removed last (TECH FIG 2G).

- This resection is a wedge resection, which includes the discs above and below as well as the concave area of the disc.

- The disc material should be removed with a pituitary rongeur and curettes; the dura and its contents are protected with a nerve root retractor.

- If the disc material above and below is not removed, correction will be limited, and anterior fusion will be less reliable.
**Closure of Wedge Resection**

- We place resected vertebral cancellous bone as well as allograft clips into the wedge resection site anteriorly.
- We have found that it is beneficial to compress and close the resection site with laminar hooks and by external three-point pressure on the body (TECH FIG 3A).
  - We place a downgoing supralaminar hook at the superior level and an upgoing infralaminar hook on the inferior level.
  - We place a rod and compress with closure of the resection site and correction of the deformity. Using this rod avoids having to place large compression forces across pedicle screws. This allows the screws to maintain correction without possible plowing of the screws into the immature bone or pedicles.
- The compression should be slow and controlled, with the dura under visualization so that it is not caught in the closure of the posterior elements (TECH FIG 3B,C).
  - If insufficient correction is achieved or if the adjacent laminae abut prematurely, it may be necessary to resect further along the edges of the laminae.
- Two additional rods are then placed, one on either side of the spine, connected to the corresponding screws. A crosslink should be applied if at all possible (TECH FIG 3D).
- The spine is then decorticated. We prefer to place corticocancellous allograft, because it is effective and avoids harvesting the iliac crest.

D. Further resection down the pedicle (arrow), with lateral structures protected.  
E. Complete visualization of the vertebral body (arrow) with anterolateral protection.  
F. Axial schematic illustration of working down the pedicle with medial and lateral protection.  
G. Arrow points to the area of complete resection.
**Anteroposterior Excision**

- We routinely place our posterior implant anchors before performing any resection. Once complete exposure (both anterior and posterior) has been performed (TECH FIG 4A), posterior screws are placed.
- Anterior resection begins by creating a full-thickness subperiosteal flap over the hemivertebra after localization is confirmed (TECH FIG 4B).
- Starting at the inferior endplate of the adjacent superior body and the superior endplate of the adjacent inferior body, we create longitudinal full-thickness cuts in the periosteum.
  - At the endplate region, we make anteroposterior cuts in the periosteum and start a full-thickness periosteal flap, working anteriorly to the contralateral side.
  - We move posteriorly until we can visualize the hemivertebra pedicle.
- The discs above and below the hemivertebra are resected all the way posteriorly to the posterior longitudinal ligament.
- We then start resection of the hemivertebra vertebral body back to the posterior cortical wall of the body with rongeurs and a diamond-tipped burr.
  - The posterior wall can be resected and peeled off the posterior longitudinal ligament with a rongeur, obtaining access by starting at the level of the disc resections.
  - Part of the visualized pedicle can be resected.
- Posterior resection can then begin, starting with the hemilamina and proceeding to the pedicle (TECH FIG 4C).
- With both incisions open and fields exposed, resection of the pedicle can be done by working through both regions (TECH FIG 4D). This allows complete visualization and maximum control of the surgical field.
- Once the hemivertebra has been resected, correction of the deformity is the same as described earlier, using a three-rod technique if possible (TECH FIG 4E).
- With this technique, correction is aided by unbreaking the table (or removing any lateral bolster) and pushing down on the convex spine to facilitate closure of the wedge resection.
POSTOPERATIVE CARE

- The immediate postoperative hospitalization and care are similar to that for most patients being treated for spinal deformity.
- When fixation is adequate, we place the patients in a custom-molded thoracolumbosacral orthosis for 3 months.
- In patients who are younger than 2 years of age, or in cases where fixation is not adequate, we recommend a Risser-type cast, to include a shoulder or both thighs for 2 months, followed by a brace for up to a total of 6 months postoperatively.
- The removal of spinal implants is not mandatory; however, given the young age of the patients and individual body habitus, occasionally it is necessary to remove the implants after a year secondary to prominence.

OUTCOMES

- Hemivertebra excision may be performed as a posterior-only technique or as a combined anterior–posterior technique, with excellent curve correction of approximately 70% (FIG 4).6
- The rate of union for this procedure is near 100% in pediatric patients.
- The procedure may be performed safely using either technique with no neurologic complications.

COMPLICATIONS

- Inadequate correction
- Dural injury
- Neurologic injury
- Loss of fixation
- Implant failure
- Excessive blood loss
- Nonunion
- Infection

REFERENCES

FIG 4 • Correction of deformity. A. Postoperative standing radiograph after excision and curve correction of patient shown in Figure 2A. B. Standing lateral radiograph of the same patient showing excellent sagittal balance after excision.
DEFINITION

- Spondylolisthesis refers to translation of one vertebra in relation to another in the sagittal plane.
- In the child and adolescent, this most commonly occurs at the L5–S1 junction.
- Most patients are asymptomatic.
- Most patients commonly present for low-grade back pain and not for radicular symptoms.

ANATOMY

- Pars interarticularis includes portions of the lamina, transverse processes, and pedicle.
- There is anterior forward slippage of the fifth lumbar vertebral body on the sacrum.
- In longstanding cases, the superior endplate of the sacrum becomes dome-shaped, and accordingly the inferior endplate of L5 becomes concave and beaks at the anteroinferior corner (FIG 1).
- The transverse processes are often hypoplastic.
- The posterior elements of L5 are detached (Gill fragment).
- The nerve roots of L5 are draped over the dome of the sacrum.

PATHOGENESIS

- In spondylolisthesis the pars interarticularis is either elongated or discontinuous.
- An isthmic defect is the result of chronic loading of a pars interarticularis that is genetically predisposed to fatigue failure.
- A dysplastic slip is secondary to congenital anomalies of the lumbosacral articulation, including maloriented or hypoplastic facets and sacral deficiency. The pars is poorly developed, allowing for elongation or eventual separation and forward slippage.

NATURAL HISTORY

- Isthmic
  - Most patients have mild or no symptoms.
  - Most present with some degree of slip.
  - Less than 4% demonstrate slip progression.
- Dysplastic
  - Risk factors for progression include diagnosis before the adolescent growth spurt, girls, and greater than 50% slip.
  - Higher frequency of progression
  - More likely to have neurologic problems
  - More likely to require operative treatment

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically present with low back pain of insidious onset, occasionally with radiation to the buttock or posterior thigh.
- Radicular symptoms and disturbance of bowel and bladder function are rare with spondylolysis or low-grade spondylolisthesis but may be reported with high-grade slips.
- Specific physical activities and sports participation (sports with repetitive hyperextension of the lumbar spine—for instance, football linemen, gymnasts, divers)
- Tight hamstrings are common, resulting in a mild crouched gait.
- Inspection, palpation, and range of motion
  - Flattened lumbar lordosis
  - Heart-shaped buttocks
  - Sacrum appears vertically oriented
  - Visible or palpable step-off at the spinous processes of the involved levels (FIG 2)
  - Limited lumbar flexion and extension
  - Lumbar hyperextension frequently will elicit pain
- Neurologic examination
  - Lumbar sensory and motor root testing
  - Evaluation of deep tendon reflexes and abdominal reflexes
  - Rectal examination indicated in patients with bowel or bladder dysfunction
- Straight leg-raise testing to assess nerve root irritation and popliteal angle measurements to assess hamstring spasm and contracture
Popliteal angles greater than 40 degrees indicate significant hamstring tightness; this is the most common neurologic finding in patients with spondylolisthesis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Standing posteroanterior (PA) and lateral radiographs of the entire spine
  - Standing PA radiographic view allows for evaluation of coexisting scoliosis secondary to paraspinal spasm, whether idiopathic or olisthetic.
  - Standing lateral view is useful for assessing global sagittal balance.
  - Spot lateral view of the lumbosacral junction is useful for identifying spondylolytic defects and documenting the degree of spondylolisthesis (**FIG 3A**).
  - Supine lateral hyperextension view of lumbosacral junction to assess passive reduction of L5 on S1.

**Meyerding classification**

- Quantifies amount of forward translation
- Based on percentage subluxation of L5 on S1 (**FIG 3B**)
  - Grade I: less than 25%
  - Grade II: 25% to 50%
  - Grade III: 50% to 75%
  - Grade IV: 75% to 100%
  - Grade V (spondyloptosis): more than 100%

**Slip angle**

- Quantifies degree of lumbosacral kyphosis.
- Line drawn parallel to superior border of S1 unreliable because of the rounding of the superior sacrum occurring secondary to the slip.
- Angle subtended by intersection of a line drawn along the superior endplate of L5 and the perpendicular of a line drawn along the posterior cortex of the sacrum (**FIG 3C**).
- Slip angle greater than 50% is associated with a greater risk of slip progression, instability, and development of postoperative pseudarthrosis.

**Single-photon emission computed tomography (SPECT) of the lumbosacral spine**

- Limited utility in spondylolisthesis.
- Most effective method for detecting spondylolysis when plain radiographs are normal and patient history and physical examination are suggestive.
- Increased radionuclide uptake in an intact pars, lamina, or pedicle is consistent with stress reaction (can treat).
- Relative decrease in tracer uptake on serial SPECT scans has been correlated with improvement of clinical symptoms and signs in patients treated for symptomatic spondylolysis.

**Computed tomography (CT) with sagittal and coronal reconstructions is the best modality for defining the bony anatomy (**FIG 3D**).**

- CT can evaluate for degree of cortical disruption, lysis, and sclerosis at the pars, lamina, or pedicle.
- 2D and 3D CT reconstruction of the spine is useful to clarify the pathoanatomy of the region for preoperative planning.

**Magnetic resonance imaging (MRI)**

- For evaluation of the health of the L4–L5 disc (if viable, try to preserve level; if desiccated, include in fusion).
For evaluation of posterior protrusion of the L5–S1 disc. Reduction at this level can cause herniation of the disc, resulting in cauda equina syndrome (FIG 3E).

NONOPERATIVE MANAGEMENT
- Most children and adolescents with low-grade spondylolisthesis respond to nonoperative measures, including activity restriction, physiotherapy, and brace treatment.
- Low-grade isthmic spondylolisthesis rarely progresses and can be followed with serial radiographs at 6-month intervals until the patient is skeletally mature. After this, radiographs can be done on a yearly basis.
- Patients with low-grade dysplastic spondylolisthesis are at greater risk for progression, development of neurologic deficit, and need for operative intervention.
- High-grade spondylolisthesis (over 50% slippage) responds less reliably to nonoperative measures.
- There is no evidence to support prophylactic fusion for asymptomatic high-grade isthmic spondylolisthesis.
- Physical therapy is the mainstay of treatment, with emphasis on hamstring stretching. It is our observation that patients who can overcome their hamstring tightness and spasm tend to have less pain and fare better. Persistent tightness of the hamstrings is associated with continued pain and, perhaps, an ultimate need for operative treatment.

SURGICAL MANAGEMENT
- Indicated for the child with persistent low back or leg pain.
- Rarely indicated in patients with less than 50% slippage. In these patients, all efforts at nonoperative treatment should be exhausted before an operation is considered, as it is known by natural history that the chance of progressive slippage is low.
- Indicated for the symptomatic, skeletally immature or mature individual with greater than 50% slippage.
- Based on the patient’s degree of slippage and symptoms, several operative options are available.
- Posterolateral in situ fusion
  - Gold standard, with longest follow-up.
  - Reserved for patients with no neurologic symptoms.
  - Does not correct deformity unless patient is postoperatively placed in a hyperextension bilateral pantaloon spica cast.
  - With or without instrumentation. Use of instrumentation can obviate the need for postoperative immobilization and may increase fusion rates.
  - Postoperative immobilization ranges from nothing to a brace with thigh extension to a bilateral pantaloon spica cast.
  - Gill procedure (removal of posterior elements of L5) is done if preoperative neurologic symptoms are present or reduction is planned.
- Bohlman posterior transsacral arthrodesis
  - Can be used with or without instrumentation
  - Can reduce slip angle
  - Can provide anterior interbody support through a posterior-only approach
  - Provides opportunity for decompression of L5 and S1 nerve roots
- Instrumented posterolateral fusion with reduction of L5–S1, posterior lumbar interbody fusion, and sacral dome osteotomy
  - Extensive, time-consuming procedure
  - Sacral dome osteotomy effectively shortens the spine and allows for posterior translation of L5 on S1
  - Gill procedure at L5 to allow for displacement after reduction
  - Requires exploration and decompression of L5 and S1 nerve roots
  - Anterior interbody support is achieved by L5–S1 discectomy and posterior lumbar interbody fusion procedure

Preoperative Planning
- Type of incision (midline versus transverse curvilinear)
- Will decompression be needed?
- Should fusion extend to L4?
- What type of bone graft will be used?
- Will instrumentation be used?
- Will postoperative immobilization be used?
- Consultation with neuromonitoring for preoperative baseline somatosensory evoked potentials (SSEPs) and electromyographic (EMG) studies
- Consultation with urology for urodynamic studies

Positioning
- Neurologic monitoring leads are placed for SSEPs and EMGs.
- Multiple large-bore intravenous lines, an arterial line, and a Foley catheter are placed.
- The patient is then transferred to the prone position on a standard operating table, with care taken to ensure that the hips are at the level of the table joint so that flexion and extension of the lumbar spine can be controlled by movement of the table.
- Extension of the hips may direct the superior endplate of the sacrum toward the inferior endplate of L5.
- Flexion of the hips may allow for more of a passive postural reduction (FIG 4).
- Bolsters underneath the chest and anterior superior iliac spines prevent abdominal compression and allow epidural venous return, thus decreasing epidural bleeding during spinal surgery.
- All bony prominences are well padded, including medial elbows, knees, shins, and ankles.
- A lateral fluoroscopic image is taken at the lumbosacral junction to see if passive postural reduction has occurred.
- After the patient is properly positioned on the table, baseline neurologic monitoring is obtained before the start of the procedure.

Approach
- We prefer a standard midline incision from L4 to the sacrum.
- This allows for bilateral posterolateral exposure of the spine out to the tips of the transverse processes.
- If desired, bone graft can be harvested from both ilia.

FIG 4 • Patient positioning. Note flexion of hips.
EXPOSURE

- The patient is prepared and draped in the standard fashion.
- A PA fluoroscopic image is taken to verify levels.
- The incision is marked and Marcaine with epinephrine is injected along the course of the incision for local anesthesia and hemostasis.
- The skin is sharply incised with a no. 15 blade scalpel and retractors are placed.
- Electrocautery is used to dissect through the subcutaneous fat until the fascia is reached.
- The spinous processes are identified via palpation. Care needs be taken at the L5–S1 level because of the displacement of L5 on S1 (TECH FIG 1).
- Bovie cautery is used to subperiosteally expose the posterior elements out to the tips of the transverse processes.
- At L5 the transverse processes are very deep within the wound.
- Care needs be taken while exposing the transverse processes as the nerve roots lie anterior to them.
- The sacrum is exposed posterolaterally out to the level of the ala.

INSTRUMENTATION

- We prefer to place the pedicle screws before performing the decompression and reduction.
- Fluoroscopic imaging is often necessary when placing screws at the L5 level because of the distorted anatomy.
- We use fluoroscopic imaging for the placement of S1 screws to ensure tricortical purchase anteriorly on the sacrum.
- We have found it useful to use polyaxial screws at all levels, with reduction screws at L4 and L5.
- If difficulty is encountered while placing screws at L5, the surgeon can wait until the decompression is done and then use a Woodson elevator to palpate the pedicle within the canal.
- Placement of pedicle screws at L5 can be difficult because the surgeon must direct the screws in an awkward trajectory.
- When placing pedicle screws we prefer an exaggerated lateral trajectory to provide for better pullout strength.
- Consideration can be given to bicortical purchase (anterior penetration) with the L5 screws to increase pullout strength during reduction.

DECOMPRESSION

- Decompression is done if preoperative neurologic symptoms exist or if a reduction is planned.
- Both lamina and the spinous process of L5 are removed en bloc (Gill fragment; TECH FIG 2A).
- The L5 nerve roots are identified and are traced from their exit from the dura out the neural foramina. It is crucial that the nerve roots be decompressed if a reduction is to be considered (TECH FIG 2B).
- The S1 nerve roots are often found draped over the sacrum, and again care should be taken that adequate space exists for their displacement after reduction.

ROD PLACEMENT

- Rod length should be measured and an exaggerated lordosis will be needed to be bent into the rod. If this is not done, the surgeon risks pullout of the L5 screws during rod placement (TECH FIG 3).
- The amount of lordosis will depend on the amount of reduction desired: if no reduction is planned, the rod will have more lordosis to allow for in situ placement.
- Conversely, reduction of L5 can also be achieved by distraction at L4–S1.
- Reduction screws greatly facilitate rod placement at both L4 and L5.

BONE GRAFT

- During the initial exposure of the spine, all soft tissue attachments should have been removed from the posterior elements.
- The facet joints are best removed with a large rongeur.
- The posterior elements are decorticated with a burr.
- Large amounts of bone graft are placed in the posterolateral gutters. An attempt should be made to place bone anterior to the tips of the transverse processes.
- When a Gill procedure is done, this unfortunately removes surface area for fusion at the lumbosacral junction.
- Care should be taken that no bone graft fragments impinge on the exiting nerve roots.

CLOSURE

- At our institution, before closure the wound is assessed for any frank bleeding vessels and bone graft is placed. Drains are placed for wounds considered at risk for hematoma formation.
- Fascia is closed with figure 8 braided absorbable suture (no. 1 Vicryl). The goal is a watertight closure.
- Subcutaneous layers are closed with interrupted braided absorbable suture (no. 0 and 2-0 Vicryl). The goal is to decrease wound tension.
- Skin is closed with a running single filament absorbable (3-0 Monocryl). The goal is cosmetic closure.
- Skin closure is reinforced with 1-inch 3M Steri-Strip Adhesive Tape Closures and surgical adhesive (Mastisol Liquid Adhesive).
- Sterile compression dressings are applied to decrease the risk of postoperative hematoma.
- Extreme care needs to be taken when transferring the patient to the stretcher.
- An assistant is needed to hold the hips and knees flexed at 90 degrees during transfer.
- Pillows need to be placed under the thighs to hold the hips and knees flexed.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Bovie electrocautery</th>

<td>Neurologic monitoring with preoperative baseline studies</td>
<td>Helps minimize risk of neural injury</td>
</tr>
<tr>
<td>Postoperative neurovascular checks</td>
<td>Neurovascular checks must be done frequently postoperatively and all lumbar nerve roots must be tested</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Careful neurologic examinations need to be performed postoperatively, especially if a reduction has been done. All lumbar nerve roots need to be tested.
- The Foley catheter is removed on postoperative day 2 and urinary function is closely monitored.
- If the plan is for the patient to be placed in a spica cast, he or she is returned to the cast room 1 week after surgery and placed on a Risser table in hyperextension. A pantaloon hip spica cast is applied.
- If instrumentation is used, no postoperative immobilization is required.
The hips and knees are progressively extended (pillows removed) as tolerated. This may take several days.

- Patient may be out of bed to a chair the morning after surgery with the hips and knees flexed.
- Ambulation is progressed as the patient is able to tolerate increased flexion at the hips and knees.
- The patient is followed clinically and radiographically at monthly intervals to assess progress (FIG 5). Consideration should be given to performing a CT scan at 6 months to assess the quality of the spinal fusion mass.

OUTCOMES

- If reduction is performed, there may be an improvement in clinical appearance.
- Hamstring spasm is often relieved after operative intervention.

COMPLICATIONS

- Wound hematoma
- Infection
- Pseudarthrosis
- Urinary retention may require prolonged use of a Foley catheter or intermittent straight catheterization.
- Neurologic injury
  - The risk of neurologic complication increases with the amount of reduction performed.
  - Motor deficits that are detected at the conclusion of the procedure are probably best treated with exploration and release of correction.
  - Fortunately, most motor deficits will improve with time, although improvement and recovery may take several months.
  - Postoperative radicular-like symptoms are managed with close observation and liberal use of gabapentin.

REFERENCES

DEFINITION

- **Spondylolisthesis** is the forward displacement of a vertebra over the next adjacent segment.
- In children and adolescents, this most commonly occurs in the presence of a spondylolytic defect or a nonunion of the pars interarticularis. It also may occur in the presence of inherent spinal anomalies such as deficient or maloriented lumbar and lumbosacral facets.
- Spondylolisthesis has been grouped into five different types under the Wiltse-Newman classification: dysplastic, isthmic, degenerative, traumatic, and pathologic.
  - Ordinarily, the dysplastic and isthmic types apply to children (FIG 1A).
- The Meyerding classification is used to grade the degree of slippage (FIG 1B). The classification is divided into five grades:
  - Grade I: 0 to 25% slip
  - Grade II: 26% to 50% slip
  - Grade III: 51% to 75% slip
  - Grade IV: 76% to 100%
  - Grade V: corresponds to spondyloptosis
- Anterior slippage of 50% or more (Meyerding grade III or IV) of the transverse width of the caudal segment is termed a high-grade slip.

ANATOMY

- The vertebral bodies have a tendency to increase in size with progression caudally. This increase is believed to be related to the demands of increased stress and weight bearing placed on the lumbosacral spine.
- The lumbar vertebrae are widest in transverse diameter than in the anterior-posterior plane. The lumbar foramina appear trefoil-like. The spinous processes are large and have an oblong appearance. Its transverse processes are long and slender and project directly lateral. The facet joints of the lumbar spine are oriented more toward the sagittal plane, allowing for more flexion and extension motion.
- The neurovascular structures in the lumbar spine run a similar course when compared to the thoracic spine. The segmental vasculature arises directly from the aorta and run dorsally around the lateral aspect of each vertebral body. Branching occurs near the pedicles, where one branch supplies the spinal...
canal and the other supplies the paraspinal musculature. These vessels run between the transverse processes, where they may be susceptible to injury in more lateral exposures.

- The spinal cord ends most commonly at the level of L1–2. The conus medullaris extends from the most distal portion and goes on to innervate the bowel and bladder. Beneath the conus, the lumbar and sacral nerve roots are arranged to form the cauda equina. Each of these roots exits segmentally below the pedicle of the corresponding vertebrae.

- The pedicles are cylindrical structures that bridge the posterior elements of the spine with the vertebral body. The height and diameter of the pedicles increases from the thoracic to the lumbar spine. The transverse diameter of the pedicle gradually increases from L1 to L5. The transverse angulation of the pedicles is directed medially, increasing gradually from L1 to L5. The sagittal plane orientation of the lumbar spine pedicles is neutral.1,8,20

- The spinal cord and the dural sac lie medial to the pedicles. Corresponding nerve roots are found both superior and inferior to each pedicle, with the inferior nerve root in closer proximity to the pedicle.1,20

- The orientation of the facet joints in the lumbar and lumbosacral spine is related to function. In the upper part of the lumbar spine, the orientation of the joints allows for multidirectional stabilization. This is in contrast to the lumbosacral facet joint, which is flat and more coronally oriented and acts to resist shearing forces through the joint.7

PATHOGENESIS

Spondylolisthesis is a disorder related to upright posture, increasing the forces acting upon the lower segments of the spine, and is never seen in the nonambulatory individual.

- The lumbar spine is subject to high shear forces and compressive loads. The “bony hook,” consisting of the pedicle, the pars interarticularis, and the inferior facets, provides stability by resisting these shear forces and preventing forward slippage or sliding over the inferior endplates.

- In the setting of congenital or dysplastic spondylolisthesis, the spine begins to slip even if the posterior elements are intact. This is brought about by the structural abnormality’s inability to resist the load and shear forces seen in the lumbosacral spine.

- In the isthmic type of spondylolisthesis, secondary to a pars defect, the high shear and compressive forces occurring through the lumbar spine and lumbosacral joint are less well resisted. This is due to the loss of posterior restraint, allowing forward displacement of one vertebral segment over the next more caudal level.7

NATURAL HISTORY

- Harris and Weinstein10 reviewed 38 cases with high-grade spondylolisthesis treated nonoperatively and with in situ fusion with a mean follow-up of 24 years and showed that 36% of patients treated nonoperatively were asymptomatic, 55% had back pain, and 45% had neurologic symptoms.

- Beutler et al,1 in a 45-year follow-up study of 30 patients diagnosed with spondylolysis, screened in the 1950s from a pool of 500 first-grade children, showed that no patients with unilateral pars defects developed spondylolisthesis. They also showed that cases with bilateral pars defects and low-grade slips follow a course similar to that seen in the general populace. Slowing of slip progression was observed with each decade.

- In a comparison of the progression of the slip between isthmic and dysplastic types of spondylolisthesis, dysplastic types showed increased progression.15

PATIENT HISTORY AND PHYSICAL FINDINGS

- In symptomatic patients, the most common clinical manifestation is low back pain, with or without radicular pain radiating through the L5 or S1 dermatome. Onset of pain is usually chronic and insidious, but acute episodes do occur.

- In patients with radicular symptoms, unilateral involvement is more common.

- Flattening of the lumbar lordosis is commonly seen on physical examination (FIG 2).

- Abnormal gait exemplified by a hip-flexed, knee-flexed gait pattern may be present.

- Hamstring tightness, which also may be present, is tested by measuring the popliteal angle. Many patients with high-grade slips will have a tendency to develop tight hamstrings owing to the development of abnormal biomechanics in the lumbar spine.

- Straight leg raise should be done to test for nerve root compression or hamstring tightness. A positive examination with radicular pain denotes either an L5 or S1 nerve root compression. Radicular pain elicited before 70 degrees is indicative of root compression, whereas that elicited above 70 degrees might denote extraspinal compression of the sciatic nerve. Pain in the posterior thigh denotes hamstring tightness.

- A rectal examination should be done in the presence of bladder and bowel dysfunction.

- Examination should also include the Lasgues test. If the pain is exacerbated, that finding supports the diagnosis of a nerve root compression. Posterior thigh pain secondary to tight hamstrings will not be aggravated.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Initial imaging includes standing posteroanterior and lateral radiographs of the spine as well as oblique views (FIG 3A–C).

- Plain radiographs are used to establish the overall alignment of the spine in both the coronal and sagittal planes. The
sagittal alignment should be noted, particularly the degree of lumbar lordosis above the lumbosacral kyphosis. Any structural abnormalities in the spine aside from the slip should be noted. These abnormalities include the presence of spina bifida occulta, scoliosis, or sagittal plane abnormalities. Other spinal problems should be treated as separate entities.

- CT scans are valuable in defining the exact bony abnormality and will help in preoperative planning (FIG 3D,E).
- MRI studies are indicated when there is evidence of neurologic compromise. MRI provides good visualization of nerve root or cauda equina compression (FIG 3F).

**DIFFERENTIAL DIAGNOSIS**
- Mechanical disorders: trauma, overuse syndromes, herniated disc, slipped vertebral apophysis
- Developmental disorders: Scheuermann’s kyphosis
- Inflammatory disorders: discitis, vertebral osteomyelitis, calcific discitis, rheumatologic conditions
- Neoplastic disorders

**NONOPERATIVE MANAGEMENT**
- The treatment of high-grade spondylolisthesis is surgical. Even in asymptomatic cases, the risk of progression or the development of cauda equina syndrome warrants surgical intervention.

**SURGICAL MANAGEMENT**
- The first goal of surgical management is to avoid complications (“first do no harm”).
- Surgical management is indicated in high-grade slips, with or without the presence of neurologic compromise, or in refractory symptomatic patients.
- Selecting the appropriate surgical intervention for each patient requires:
  - A thorough evaluation of the deformity
  - An in-depth understanding of the nature of the pathology
  - An understanding of the indications for treatment
  - Awareness of the limitations of each procedure and its possible complications

**FIG 3** • PA (A), lateral (B), and left and right oblique (C) radiographs demonstrating high-grade spondylolisthesis. Axial (D) and sagittal (E) CT scan sections demonstrating bony deformity. F. MRI demonstrating high-grade spondylolisthesis.
Preoperative Planning
- A detailed assessment of the history and physical and neurologic examinations should be performed.
- All imaging studies must be carefully reviewed and analyzed with attention to trying to correlate physical and neurologic findings with those found in special examinations.
- The degree of the slip as seen on the lateral standing spine radiographs is assessed and graded according to the Meyerding classification.
- Slippage of 50% or more is considered a high-grade slip.
- The slip angle measures the degree of lumbosacral kyphosis.
- A slip angle greater than 50 degrees is associated with progression, instability, and pseudoarthrosis (FIG 4A).
- Pelvic incidence (PI) is a fixed anatomic parameter that estimates the position of the sacral endplates and overall pelvic morphology. It helps determine the overall sagittal profile of the spine.3,12
  - The PI increases with age and stabilizes in adulthood.14
  - The mean PI is 47 degrees in children and 57 degrees in adults.
  - Increased PI is indicative of increased lumbar lordosis and increased shear forces (FIG 4B). Increased PI may predispose to the development of spondylolisthesis.3,11,12
  - In the presence of spondylolisthesis, an increased PI may be indicative of an unbalanced pelvis and is a risk factor for slip progression. Slip reduction is required in these cases to restore proper spinopelvic biomechanics and stabilize the spine. In those cases, where the spine is balanced and PI is low, a fusion in situ may be all that is required for treatment.

Positioning
- The patient is positioned prone on the operative frame.
- Two operative positions are commonly used for posterior approaches to the spine.
  - The first is the knee-chest position, where both the hips and knees are flexed.
  - The second position is with the use of a four-poster frame, where the lower extremities are fairly parallel to the trunk. In this position, the patient is supported under the anterior superior iliac spines and pectoral muscles bilaterally.
  - Our preference is to place the patient in the Jackson spinal table with the hips and knee in the flexed position, allowing for easier access to the lumbar spine.
- The position of the face and arms is important. The face should be adequately supported, making sure that no excessive pressure is applied, especially around the orbits. The neck should be in neutral position. The upper extremities should also be in 90–90 position, in which the arms are in 90 degrees of abduction and the elbows are in 90 degrees of flexion. The upper extremities should be adequately padded to allow for venous and arterial access. Adequate padding, support, positioning, and monitoring of the upper extremities likewise prevents undue neurologic injury due to stretch or excessive pressure.19

**ROUTINE REVISION WITHOUT DIAPHYSEAL DEFECT**

**Bohlman Technique**
- In the Bohlman technique,22 the procedure starts with a standard posterior midline approach extending from the second lumbar vertebra to the level of S2.
- The spine is exposed subperiosteally, revealing all the posterior elements.
- The posterior elements of L5 and S1 are removed (the posterior elements of L4 are removed if needed).
- A wide foraminotomy is performed to decompress the L5 and S1 nerve roots.
- The dura is gently freed and retracted.
- A curved osteotome is used to make a ventral trough through the sacrum to remove pressure from the dura (TECH FIG 1A).
- The dura is retracted, and a ½-inch guide pin is placed in the midline of the sacrum toward the body of L5. This is done under fluoroscopic guidance to ensure proper placement.
- A ½-inch cannulated drill bit is used to drill over the guide pin, taking extra care not to violate the anterior cortex of L5. The depth is approximately 5 cm.
- A mid-diaphyseal fibular graft is trimmed to fit into the drill hole and inserted (TECH FIG 1B). The position of the graft is confirmed fluoroscopically.
- Alternatively, a split fibular graft can be inserted as described by Bohlman in 1982.2
- This is performed by inserting a guide pin through the posterior prominence of the sacrum approximately one cm from the midline to the body of L5, avoiding the first sacral nerve root. The position of the guide pin is confirmed radiographically. This process is done bilaterally.
A wide laminectomy is performed removing the posterior elements of L5 and S1. The dura is retracted gently, and a curved osteotome is inserted to perform a sacroplasty to take pressure off the dura. A fibular strut graft is fashioned and inserted into the sacrum to the body of L5. The procedure is then completed by performing bilateral posterolateral fusion.

- A 3⁄8-inch cannulated drill bit is used to drill over each guide pin, taking extra care not to violate the anterior cortex of L5. The depth is approximately 5 cm on both sides.
- A fibular graft is split in half and trimmed. It is then inserted and countersunk 2 mm into each hole.
- A standard posterolateral transverse process fusion is done, extending from the sacral alae to L4, to complete the procedure.

### Children’s Hospital of Philadelphia (CHOP) Technique

#### Incision and Dissection

- The lumbar spine is approached posteriorly through a direct midline incision extending from L2 to S2 (TECH FIG 2A).
- The dissection is done using loupes for magnification and head lamps for illumination.
- The midline incision is carried down to the fascia through sharp dissection of the skin and subcutaneous tissue.
- The midline dissection is carried down subperiosteally, exposing the posterior elements of the spine, with care taken to protect the most proximal intact facets (TECH FIG 2B,C).
In isthmic spondylolisthesis, removal of loose bodies and the posterior elements of L5 is done.

**Decompression**

- The nerve roots of L5 and S1 are identified, and a wide decompression of the L5/S1 roots is carried out bilaterally (TECH FIG 3A).
- The dura and neural elements over the sacrum are gently retracted, and a sacroplasty is done using an osteotome or a high-speed diamond burr (TECH FIG 3B).

**Reduction and Fusion**

- Pedicle screws are placed into the L4, L5, S1, and S2 pedicles (TECH FIG 4A).
- The anesthetic and spinal monitoring team is informed before any corrective maneuvers are performed.
- The reduction is performed under fluoroscopic guidance, avoiding overcorrection. With the use of reduction tools...
attached to the pedicle screws, the slip angle is gradually reduced under fluoroscopic guidance by applying a dor- sal extension maneuver to the lumbar pedicle screws (TECH FIG 4B).

- The reduction is performed slowly and maintained over time to allow for stretch of the soft tissue. Once a satisfactory correction of the slip angle has been achieved, gradual reduction of the slip is performed by applying force to the sacrum, while a counterforce is applied to the lumbar spine (TECH FIG 4C).

- Reduction of the slip angle is much more important than reduction of the slip itself. Close attention to spinal cord monitoring is crucial during the entire reduction maneuver.

- The rods are templated, cut, and contoured, and then attached to the construct while reduction is maintained.

- Final tightening of the entire construct is done and checked with fluoroscopy or plain radiographs (TECH FIG 4D).

- The L5–S1 disc is identified and removed, a fusion is performed, and the L5–S1 disc space is filled with cancellous autograft or allograft.

- An anterior cage is placed to provide adequate anterior column support (TECH FIG 4E).

- As an alternative, a double split fibular strut graft (modified Bohlman technique) can be inserted from the sacrum to the body of L5 to add anterior column support. The dura is gently retracted to one side, and a guide pin is inserted from the sacrum to the body of L5 (TECH FIG 4F).

- A 6-mm cannulated reamer is then used to ream this channel (TECH FIG 4G).

- A fibular auto- or allograft is then placed through the channel and countersunk (TECH FIG 4H).

- The same procedure is repeated on the contralateral side.

- The procedure is completed by placing bone graft lateral to the implants along the transverse processes from L4 to the sacrum.

- Meticulous hemostasis is carried out, and a layer-by-layer closure of the operative site is performed.

**PEARLS AND PITFALLS**

<table>
<thead>
<tr>
<th>Indications</th>
<th>■ A complete history and physical and neurologic examination must be performed before surgery.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>■ All needed and appropriate imaging studies must be evaluated carefully to identify all aspects of the deformity—including the degree of the deformity and the type (eg, isthmic vs congenital)—as well as any other spinal deformity that may be present (eg, spina bifida occulta).</td>
</tr>
<tr>
<td>Surgical exposure</td>
<td>■ Careful and meticulous technique must be observed. Care should be taken, especially when pathologies such as spina bifida occulta are present, to prevent iatrogenic neurologic injury.</td>
</tr>
<tr>
<td></td>
<td>■ Decompression of at-risk nerve roots is a key component to exposure and operation.</td>
</tr>
<tr>
<td>Instrumentation</td>
<td>■ Careful preparation should be undertaken before performing instrumentation and reduction.</td>
</tr>
<tr>
<td></td>
<td>■ Adequate decompression of all neurologic structures at risk should be ensured to prevent iatrogenic injury.</td>
</tr>
<tr>
<td></td>
<td>■ Close attention must be paid to neurophysiologic monitoring during both instrumentation and reduction.</td>
</tr>
<tr>
<td>Reduction</td>
<td>■ Slow, gentle force is applied during the reduction maneuver. This procedure should be done over time to allow for relaxation of the soft tissue structures.</td>
</tr>
<tr>
<td></td>
<td>■ Avoid excessive reduction. Reduction of the slip angle is more important than complete reduction of the slip. Excessive reduction may result in neurologic compromise.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- High-quality radiographs are taken immediately postoperatively to ensure proper graft and instrumentation placement before the patient is taken out of the operative suite (FIG 5).
- In the immediate postoperative period, the hips and knees are flexed and elevated using pillows to alleviate pain.
- Pain control is institutied (eg, intrathecal analgesia and IV patient-controlled analgesia), and the patient is fitted with a thoracolumbosacral orthosis (TLSO) for comfort. The patient is then encouraged to stand and ambulate as tolerated. Postoperative anteroposterior and lateral standing spine radiographs are taken before discharge.
- Activity restriction (ie, avoidance of bending and rotational motion) is carried out until fusion has occurred.
- The patient may return to sports and strenuous physical activity after 1 year as long as spinal fusion has been confirmed. Adequate precautionary measures should be taken before engaging in any contact sport.
- Full-contact sports, which may entail collision, should still be avoided.

OUTCOMES

- In high-grade spondylolisthesis treated with in situ fusion techniques, clinical improvement in back pain symptoms has been reported in 74% to 100% of cases. Solid fusion rates have also been reported to be 71% to 100%,6,8,13,23,24

- A study on 18 adolescents with high-grade spondylolisthesis treated with instrumented reduction and fusion reports complete resolution of preoperative neurologic symptoms with 100% fusion rates. No loss of fixation or instrument-related failures were reported at a minimum of 2 years’ follow-up.21

- Another series16 comparing in situ fusion, decompression, reduction and instrumented posterior fusion, and circumferential fusion techniques in treating high-grade spondylolisthesis reports a 45% (5 of 11 patients) pseudoarthrosis rate in patients treated with in situ fusion and a 29% (2 of 7 patients) pseudoarthrosis rate in cases treated with posterior decom-pression, instrumentation, and fusion. All of these cases had small transverse processes (less than 2 cm²). Circumferential techniques achieved the highest fusion rates. Excellent functional outcomes were observed in those cases where a solid fusion was achieved. Final outcomes, however, did not differ among the three groups.

- Another study comparing posterior fusion and reduction with posterior fusion and reduction augmented by anterior column support reported a 39% pseudoarthrosis rate in posterior fusion alone. In the cases augmented with anterior column support, 100% fusion rates were achieved.16

COMPLICATIONS

- Pseudoarthrosis
  - Pseudoarthrosis is the most common complication.
  - Signs include lucency around implants, implant breakage, and slip progression.
  - Pseudoarthrosis may be minimized by using meticulous technique and proper preparation of the graft site.

- Neurologic complications
  - Root lesions (L5 root)
  - From direct trauma, manipulation of nerve roots, epidural hematoma formation (compression)
  - Cauda equina syndrome
  - Autonomic dysfunction
  - Chronic pain

- Immediate release of the correction should be done when necessary.
  - Must be thoroughly evaluated with proper imaging techniques
  - May be minimized by good preoperative planning and meticulous surgical technique and by using multimodality spinal cord monitoring

- Transition syndromes
  - Spondylolisthesis acquisita
  - Adjacent segment degeneration
  - S1–S2 deformity
  - Instrument-related complications
REFERENCES

**DEFINITION**
- The treatment of neuromuscular spinal deformities frequently requires fusion to the pelvis with firm fixation. This can be accomplished with a number of devices that allow for correction of pelvic obliquity and pelvic rotation while allowing for a solid base on which to attach rods for correction of curves above.
- One of the most reliable structures in the formation of the spine, even in the dysplastic setting of myelomeningocele, is the sacral ala.
  - The S-rods are contoured to press-fit over the sacral ala.\(^1\,3\,4\)
  - Historically the elongated Harrington hooks were used in a similar manner.

**ANATOMY**
- The sacral ala in children is a structure 1.5 to 2 cm in depth (front to back) and 2 to 3 cm wide.
- The L5 nerve root traverses anterior to the ala in an oblique direction progressing from posterior to anterior and superior to inferior obliquely from the neural foramina.
- Immediately inferior to the pedicle of L5 the nerve transgresses anterior to the sacral ala, separated by a distance of 1.5 cm.
- Besides the L5 root, the tissue anterior to the sacral ala is retroperitoneal fat.

**PATHOGENESIS**
- The multiple types of neuromuscular scoliosis requiring fixation to the pelvis include cerebral palsy, dystrophic muscle conditions, spina bifida, and many others.
- The types of pelvic abnormalities associated with spinal deformities include pelvic obliquity, pelvic rotation, and flexion and extension of the sacrum.

**NATURAL HISTORY**
- The natural history is one of progression and worsening of these deformities.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**
- Special imaging and other diagnostic studies are only occasionally necessary.
- The sacral ala can usually be clearly visualized as a horseshoe-shaped outline on upright or supine lateral radiographic films.
- The Ferguson view (45-degree angle) in the frontal plane provides the clearest view of the width.
- If there is doubt, a CT scan can better elucidate the exact configuration.

**SURGICAL MANAGEMENT**
- The surgical management, in terms of preoperative planning, positioning, and approach, is the same as for neuromuscular scoliosis.
- The techniques include cleaning of the soft tissues from the sacral ala with release of the ileotransverse ligament.
- The sizing of the hook to the size of the sacral ala in its front-to-back diameter can be done at surgery.
- Small and medium sizes are available, and it is important to use the appropriate size rod or hook (right or left) so the rod lies medial to the ala (**FIG 2**).
S-ROD PLACEMENT

- Proper alignment of the S-rod necessitates placement of the sagittal bends in the appropriate plane with reference to the best fit of the S-portion on the ala (TECH FIG 1A).
  - This can be aided by placement of a vise grip on the rod in the plane of the lordosis once the S-portion of the rod is positioned over the sacral ala.
  - The rod is removed from the wound and the three-point bender applied to produce the proper sagittal contours.
- If the S-hook is used instead, the sagittal contours can be made in the rod independent of the hook position.
  - It is best to leave 1 cm protruding from the lower end of the hook when it is first placed on the ala (TECH FIG 1B).
  - The S-hook is temporarily tightened to the rod and spread between the L4 pedicle screw and the S-hook by tightening one Allen set screw on the hook (TECH FIG 1C,D).
  - The correction of the spinal deformity can then occur above this area.

TECH FIG 1 • A. Posterior view of a right-sided S-rod on the spine. B. Initial position of the S-hook on the rod for placement purposes, with 1 cm of rod protruding. C,D. The S-hook shown positioned over the sacral ala and up the spine.
FINAL FIXATION

- Once the final correction has been achieved, the final tightening of the S-hook occurs by distracting once again between the L4 pedicle screw and the concave side S-hook, then the convex side rod, distracting the hooks to the end of the rod (TECH FIG 2).
  - Both Allen set screws are firmly tightened.
  - A strong cantilever force can be created to correct pelvic obliquity by using two sagittally contoured rods fixed to S-hooks positioned against the sacral ala distracted against the L4 pedicle screws.
  - A transverse rod connector above the S-hooks will supply further stability.
  - The pelvis can then be pivoted by grasping the rods above and correcting the pelvic deformity in one maneuver.
  - The final fixation of the S-hook is completed with both set screws firmly tightened.²

PEARLS AND PITFALLS

The surgeon must avoid the pitfall of thinking the transverse process of L5 is the ala and positioning the S-hook or S-rod against this structure.

- This can happen if the ileotransverse ligament is not completely released and the sacral ala clearly visualized (FIG 3).
- An L4 polyaxial pedicle screw works well to ensure proper pressure and fixation between the L4 screw and the sacral ala.

POSTOPERATIVE CARE

- It is important to maintain hip flexion at 45 degrees or greater for the first 6 months to avoid levering on the pelvis with physical therapy.
  - No physical therapy is done about the hips for the first 6 months.

OUTCOMES

- This technique has been used in more than 200 cases since 1984. Outcomes are generally solid fusions, ease of caregiving, and attainment of level pelvis for sitting (FIG 4).
COMPLICATIONS

- Rod migration into myelo pelvis with a growth rod
- I have not experienced any neurologic impairment of the L5 root.

REFERENCES

DEFINITION
- Developmental dysplasia or dislocation of the hip (DDH) is a disorder that may affect the development and stability of the hip joint during the critical period of growth, either in utero or after birth.
- This may lead to dysplasia, subluxation, or frank dislocation of the hip joint.

ANATOMY
- Growth of the hip joint is genetically and mechanically determined.
  - In the first trimester, the structures of the joint begin as a single mass of scleroblastema with a globular femoral head that becomes cartilage at 6 weeks.
  - By 8 weeks’ gestation, the start of the fetal period, vascular invasion leads to enchondral ossification.
  - The joint space develops by degeneration at 7 to 8 weeks and the structure of the joint is well apparent by week 11.
  - A round and reduced femoral head influences the concave shape of the acetabulum to develop.
  - Acetabular growth depends on interstitial, appositional, periosteal new bone and secondary centers of ossification growth.
  - In the first two trimesters of fetal life the acetabulum is a hemisphere with a depth 50% of its diameter. However, by the time of birth the depth is only 40% of its diameter, which may contribute to instability at birth.
  - The acetabular labrum, which resembles an O ring (FIG 1A), contributes considerable mechanical stability and proprioceptive feedback (FIG 1B).
  - By 8 years of age the acetabular shape is for the most part determined and thus surgical reduction is less advised, especially if the dislocation is bilateral.

There is continued growth into adolescence, with the triradiate cartilage fusing by 13 years in girls and 15 years in boys.
- Closure of the triradiate cartilage may occur earlier in the dysplastic hip.
- By adulthood the acetabular depth is 60% of its diameter.
- The proximal femur is formed initially as a single chondroepiphysis (FIG 1C), with the ossific nucleus typically appearing in infancy at 2 to 8 months of age.
- There may be some side-to-side size discrepancy in appearance.
- The greater trochanter nucleus appears at about 3 years in girls and 5 years in boys, with the lesser trochanter appearing by age 6 to 11 years.
- The femoral head vascularity is mostly from the medial and somewhat from the lateral femoral circumflex arteries. Because it is an intra-articular dome-shaped structure, this blood supply is susceptible to injury.

PATHOGENESIS
- Around the time of birth, capsular laxity, a normally shallow acetabulum, and abnormal mechanical forces, such as those seen in breech presentation, may cause the hip capsule to be lax and to dislocate.
- An absent or subluxated femoral head eventually leads to a flat, egg-shaped acetabulum, which is a consistent finding on three-dimensional computer modeling performed of the acetabulum (FIG 2A).
- With time the neolimbus, which is abnormally formed articular cartilage, can develop at the edge of the acetabulum. It can be a barrier to reduction (FIG 2B).
A steep, maloriented growth plate, intra-articular obstructions, and stunting of periosteal new bone formation all in time contribute to further deformity.

Mechanical blocks to reduction include the anteromedial capsule, ligamentum teres, psoas tendon, neolimbus, transverse acetabular ligament (which is an inferior medial extension of the acetabular labrum), and intra-articular pulvinar tissue.

An inverted labrum is rarely a block to reduction.

The average unit load of human and animal joint cartilage is 25 kg/cm².

Hips with acetabular dysplasia, and particularly with subluxation, have about 25% less contact area and more unit load (stress) per area of contact.

There is an inverse relationship between greater contact pressures and the onset of osteoarthritis.

**NATURAL HISTORY**

- Newborn period
  - About 1 in 60 infants have instability at birth, with 60% of cases resolving in the first week of life and 88% by the first 2 months. Thus, about 1.5 in 1000 have a true dislocation.²
  - Muscle activity is considered important for recovery and is the basis of the Pavlik harness success.
  - Untreated acetabular dysplasia with subluxation or dislocation
    - The natural history of hip dysplasia when subluxation or dislocation is present is predictable. The long-term outcome is worse than with acetabular dysplasia without subluxation.¹⁰
    - The onset of symptoms and radiographic deterioration is directly related to the degree of subluxation and dysplasia.

- Clinical symptoms, typically pain, may antecede the radiographic deterioration by 10 years.
- If the hip is completely dislocated, limb-length discrepancy and back and knee pain are common, while painful arthritis correlates with the presence of a false acetabulum and its adverse effect on the femoral head articular cartilage.

- Acetabular dysplasia with no subluxation
  - The natural history of acetabular dysplasia is much less predictable when subluxation or dislocation is absent.¹⁰
  - During childhood, hips that are well centered improve their acetabular dysplasia, although not always to normal, whereas the hip that is radiologically eccentric typically does not improve.
  - If the center-edge angle in the mature hip is less than 20 degrees, the hip will likely develop arthritis sometime during the patient’s lifetime. However, it is difficult to determine how early in life the deterioration will occur.
  - Although hips with acetabular dysplasia can spontaneously improve, this improvement is not predictable or necessarily complete.⁸
  - A hip with a persistently upsloping lateral margin seen on an anteroposterior (AP) radiograph generally develops arthritis by late adulthood.⁵

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- All newborn infants should receive a gentle and focused examination of the hips, including range of motion and Ortolani maneuver.
  - The physical examination of the newborn, rather than imaging studies, should determine the diagnosis of DDH and the need for treatment.
  - An Ortolani-positive hip is dislocated or subluxated and the examiner perceives that the hip partially reduces with abduction. After several months of age the hip may appear stable on examination but may still be dislocated.
  - The child is examined for any abnormal skin creases (FIG 3). Proximal skin creases may indicate a dislocated hip or a short femur. The examiner should also note the level of the popliteal skin crease, the position of the knee, and any lateral displacement of the hip.
  - A simple, high-pitched and commonly felt “hip click” is not a sign of instability or dislocation.
  - Hip instability decreases with time, whereas deformity, such as limited hip abduction, increases with time.
The young infant with a dislocated hip may have normal abduction until several months of age. There may be limited abduction in developmental coxa vara. Abduction may appear to be normal if both hips are dislocated.

The upper extremities, spine, and feet are always inspected to evaluate for possible generalized conditions such as arthrogryposis or neuromuscular conditions.

In the child of walking age, a delay of walking may be the first indicator that the hip is dislocated.

Dipping of the pelvis and shoulder (Trendelenburg gait), female profile (pelvic widening from the dislocation), and shortening of the thigh (Galeazzi sign) are classic signs of a dislocated hip in the older child.

The Galeazzi test may also be abnormal if the child has a congenital short femur.

Additional signs of Trendelenburg gait include side-to-side waddling, indicating weak hip abductors, or the examiner may see lurching, indicating weak hip extensors. The child may stand or walk with hyperlordosis. These are proximal compensations for a hip dislocation and the resulting inadequate muscle strength to support the pelvis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Ultrasound is a useful imaging method up to 6 months of age (FIG 4A).

  ![Figure 4A: Coronal section ultrasound imaging through the most posterior aspect of the acetabulum. The femoral head is well visualized dislocated from the acetabulum. The acetabulum is steep. The femoral ossific nucleus is not present. There is a break in the Shenton line on the left and it is normal on the right.](image)

  ![Figure 4B: Seven-month-old with a dislocated left hip. The acetabulum is steep. The femoral ossific nucleus is not present. There is a break in the Shenton line on the left and it is normal on the right.](image)

  ![Figure 4C-E: Radiographs of young adult with high-grade right acetabular dysplasia. On the AP pelvic view, the center–edge angle (CEA) on the left is low normal (26 degrees); on the right it is 10 degrees. The Shenton line is intact, indicating that there is no subluxation.](image)

  ![Figure 4D-E: Right hip false profile views. Right hip CEA is 0 degrees and left hip CEA is 22 degrees.](image)

  ![Figure 4F: Left hip intraoperative arthrogram shows concentric reduction. There is no pooling of the intra-articular contrast medially.](image)

The two most common indications for ultrasound imaging are for screening the asymptomatic infant considered to be at high risk for hip dislocation (girls born breech have a 133/1000 risk of DDH) and for following an infant with proven DDH, especially during Pavlik harness treatment.

The AP radiograph is most useful in infants over 6 months of age.

- In children more than 3 years of age, the Shenton line is a reliable indicator of subluxation (FIG 4B).
- The Von Rosen view in abduction and internal rotation shows the ability of the femoral head to reduce.
- In the adolescent or adult hip, a standing AP pelvis view is obtained with measurement of the center–edge angle, as well as standing false profile views of each hip joint (FIG 4C-E).
- The normal center–edge angle on the AP pelvic radiograph is greater than 24 degrees.

  Intraoperative arthrography can show whether the femoral head is fully reducible with no medial pooling of contrast (FIG 4F).

- If the femoral head does not easily reduce and remain stable without excessive hip abduction, an open reduction is used to address the extra-articular and intra-articular blocks to reduction.
- CT scanning is commonly used to evaluate the adequacy of a closed or open reduction after surgery and for preoperative planning of pelvic or femoral osteotomy.
MRI imaging, particularly with intra-articular gadolinium injection, shows labral pathology, the condition of articular cartilage, osteonecrosis, and femoral- acetabular impingement pathology.

DIFFERENTIAL DIAGNOSIS
- Septic hip dislocation: this is the most important diagnosis to consider in the young infant
- Teratologic hip dislocation (arthrogryposis)
- Neuromuscular dislocation (most commonly cerebral palsy and spina bifida)
- Traumatic hip dislocation
- Developmental coxa vara: easy to mistake as DDH before the ossific nucleus is present
- Congenital short femur
- Instability and dysplasia related to underlying condition (Down syndrome, Ehlers-Danlos syndrome, Charcot-Marie-Tooth disease); commonly bilateral

NONOPERATIVE MANAGEMENT
- The basic principles of treatment are to obtain a concentric, stable reduction while avoiding osteonecrosis, to promote normal growth of the hip, and to achieve normal long-term function.
- The treatment of DDH depends on the age of the child and thus the stage of development of the hip joint.
- Generally, the earlier that treatment is initiated, the more likely that less invasive treatment will be successful and that a better outcome will result.
- Treatment options range from observation, to a Pavlik harness (FIG 5) or other brace treatment in the young infant, to closed or open reduction and hip-spi casting, pelvic or femoral osteotomies, and salvage procedures in older patients.
- By the time of skeletal maturity, as normal as possible acetabular anatomy should be restored. Ideally, reconstructive surgery should be performed during early childhood, when the results are believed to be better and the risks acceptable.

SURGICAL MANAGEMENT
- If the hip remains dislocated or subluxated despite conservative treatment with a Pavlik harness or abduction orthosis, or if a concentric and stable reduction cannot be achieved with closed reduction and casting, open surgical reduction is appropriate.

Preoperative Planning
- For the infant who has not achieved walking age, an open reduction without associated femoral shortening or pelvic osteotomy is generally sufficient.
- With age and walking, the deformities in and around the hip become more fixed and require a more aggressive surgical approach.
- Prereduction traction is less frequently used than in the past for the infant and is not recommended for the older child. Generally, a child over age 2–3 years requires a femoral shortening osteotomy if the femoral head is displaced proximally.
- Epidural or caudal regional anesthesia may be helpful to supplement the general anesthesia.
- A type and screen is obtained, but blood transfusion is rarely required.
- An indwelling bladder catheter is used during the surgery, since much of the surgery is intrapelvic.

Positioning
- A radiolucent table is used in case an intraoperative radiograph will be obtained.
- The child is placed in a semilateral position (FIG 6).
- The entire limb is draped free.

Approach
- Several variations of the medial approach to the hip joint have been described. These are very useful in the infant if the femoral head is not excessively high and for bilateral instability surgery done the same day.
- For the older infant and child an anterior approach to the hip joint allows more extensile exposure.
- The anterior approach is especially useful if there is a false acetabulum with a high dislocation and for fixed dislocations in which the hip capsule is adherent to the hip abductors and pelvic wall.
- The anterior approach allows for an associated pelvic osteotomy through the same incision.
- The decision to perform a medial approach or an anterior approach to the hip joint will depend on the child’s age, the location and severity of the pathology, and the surgeon’s experience.

FIG 5 • Pavlik harness. This infant is comfortable in the harness; hips and knees are flexed with abduction provided by gravity, not from the lateral straps.

FIG 6 • Semilateral position. The anterior hip and lateral thigh incisions are generally parallel when the hip is flexed about 30 degrees.
ANTERIOR HIP EXPOSURE

- A modified anterior Smith-Peterson exposure with the incision placed in the inguinal crease just below the anterior iliac superior iliac spine is cosmetically appealing.
- Sharp dissection is carried deep until no more fat can be identified.
  - This is the deep fascia, which can then be further exposed distally by using a sponge on the fascia.
- If femoral shortening is anticipated, a separate direct lateral approach to the proximal femur is used.
  - Both exposures should be completed before osteotomies are performed because of increased bleeding from the bone.
- The tensor–sartorius internervous interval is easier to identify distally where the muscles are divergent (TECH FIG 1A).
- The fascia of the tensor muscle is entered slightly lateral to the fatty interval between the two muscles. The lateral femoral cutaneous nerve is identified and protected.
- Army-Navy retractors are used to separate the tensor and sartorius muscles until the rectus femoris muscle is identified.
  - This dissection is continued proximally and the prows of the pelvis are exposed between the anterior superior and anterior inferior iliac spines.
- The external oblique muscle is gently separated off the iliac crest.
- The iliac crest apophysis is divided exactly in the middle with a single cut using a no. 15 blade down to iliac bone (TECH FIG 1B).
- Periosteal elevators are used to expose the inner and outer tables of the iliac crest (TECH FIG 1C).
- Laparotomy sponges are used to help dissect deep near the sciatic notch and to pack the surgical site for hemostasis.
  - Perforating vessels into the iliac bone on the inner table are consistently present and require bone wax for hemostasis.
- Smooth Lane retractors are used to further dissect the sciatic notch both medially and laterally.
- The reflected and straight heads of the rectus femoris muscle are identified (TECH FIG 1D).
- It is extremely important for the dissection to continue medially onto the pubis by opening the interval between the iliacus and the rectus femoris muscles (TECH FIG 1E).
- By opening the medial periosteum at the level of the pubis, the iliopsoas tendon is identified, which lies deep on the iliacus muscle.
- The tendon is followed distally so that the interval between the iliacus muscle and the rectus femoris muscle is separated more deeply.
- The iliopsoas tendon is brought into the superficial surgical site with a right-angled clamp and divided at the level of the ilipectineal groove on the pubis.

TECH FIG 1 • A. Tensor–sartorius interval. Note the lateral femoral cutaneous nerve (arrow). B. The external oblique muscle has been detached off the iliac crest apophysis, which is being divided by a no. 15 blade. C. Subperiosteal dissection of the iliac inner and outer tables. D. Superior view of the left hip (patient’s head is to the right) showing the rectus femoris (RF), its straight head attachment to the anteroinferior iliac spine (AIIS), and the reflected head attaching to the hip capsule (RH). E. The iliopsoas tendon is identified, dissected distally, and divided at the ilipectineal eminence. (continued)
The femoral nerve is close by, superficial and medial to the psoas tendon.

The reflected and straight heads of the rectus femoris muscle are identified and divided. This allows skeletonization of the femoral head by separating the iliacus, rectus femoris, and hip abductor muscles off the capsule (TECH FIG 1F–H).

- A Cobb elevator is useful for separating these muscles off the hip capsule.

- It is extremely important to carry the dissection around to the deep inferior medial aspect of the hip capsule (TECH FIG 1I).

- With a Kocher clamp, grasp the proximal aspect of the reflected head of the rectus femoris tendon to further expose the capsule. The capsule must be detached from any false acetabulum on the lateral iliac wall. I. The capsule is exposed, particularly the inferior medial aspect.

OPEN REDUCTION

- A T-shaped capsulorrhaphy is made with the redundant proximal limb eventually removed.
  - The incision parallels the acetabular rim but is about a centimeter away so that the labrum is not injured (TECH FIG 2A).
  - The femoral head is examined for deformity (TECH FIG 2B).
  - The ligamentum teres is divided off the femoral head (TECH FIG 2C).
  - The stump of the ligamentum teres is grabbed with a Kocher clamp, and it is followed into the depths of the acetabulum.
    - It is essential to visualize the entire acetabulum and the transverse acetabular ligament.
    - The ligamentum teres is removed with Mayo or cartilage scissors at its deep acetabular attachment.
    - Under direct vision, a pituitary rongeur is used to remove the pulvinar tissue that lies within the acetabulum.
    - The transverse acetabular ligament is divided.
At this point the femoral head should be reducible.
- For children over 2–3 years of age, especially if the reduction is tight or unstable, a femoral shortening osteotomy is performed before the capsule is closed.
- If an acetabular osteotomy is performed, it is also completed before the capsulorrhaphy sutures are tied.
- An adductor longus and gracilis tenotomy is generally not needed but can be included if these muscles feel excessively tight.
- A capsulorrhaphy is performed by advancing the superolateral capsule to the inferior medial aspect of the capsule on the pubis (TECH FIG 2D).
- Nonabsorbable no. 0 sutures are all placed and tagged and then sequentially tied (TECH FIG 2E).
- The iliac crest apophysis is reapproximated with heavy suture and the external oblique muscle is reattached.
- The rectus femoris and iliopsoas muscles are left divided.
- A surgical drain is not required.
- A one-and-a-half spica cast is applied with the hips in a safe “human” position with no more than 30 degrees of flexion and abduction.

TECH FIG 2 • (continued) B. The hip capsule has been opened, exposing the deformed femoral head. C. The ligamentum teres is divided off its femoral head attachment. The vascular contribution of the ligamentum teres to the femoral head is minimal. D. After any associated femoral and acetabular osteotomies are performed, the capsule is advanced medially. E. Nonabsorbable sutures are placed and tied after osteotomies have been completed.

PROXIMAL FEMORAL SHORTENING OSTEOTOMY
- A straight lateral approach to the proximal femur is used.
- The tensor fascia is divided longitudinally.
- The anterior edge of the gluteus medius muscle is identified where it attaches to the greater trochanter.
- Several millimeters of the gluteus medius muscle is detached off the trochanter.
- This allows palpation of the anterior aspect of the femoral head to estimate the amount of femoral torsion (TECH FIG 3A).
- The vastus lateralis muscle is detached off the femur by dividing its proximal attachment in the transverse plane at the trochanteric ridge, leaving enough cartilage attached to the muscle to allow secure fixation during closure (TECH FIG 3B).
- The vastus lateralis muscle should be divided off the posterior intermuscular septum so that the muscle innervation is left completely intact.
- Stiff Steinmann pins are inserted in the proximal and distal femur to ensure that a proper amount of femoral rotation is provided.
- A third pin is placed up the neck of the femur to judge femoral head–neck antetorsion, and a fourth pin is placed just below the lesser trochanter to guide the osteotomy.
- A one-third tubular small fragment plate or a 2.7-mm minifrag dynamic compression plate is generally sufficient in a young child (TECH FIG 3C). A 3.5-mm dynamic compression plate is used for an older child.
The proximal aspect of the plate is fixed loosely. A subtrochanteric osteotomy is believed to be less hazardous to the hip vascularity than an intertrochanteric osteotomy. The femur is shortened by the amount that the cut ends of the femur overlap when the femoral head is reduced (TECH FIG 3D). The shortened fragment of femur can be used for holding open a pelvic osteotomy.

The plate is prebent slightly and is secured with some compression applied. The Steinmann pins are used to judge any rotation that is desired. If excessive femoral torsion was noted, some of this can be judiciously corrected. The tension band effect of the vastus lateralis muscle is restored (TECH FIG 3E). The incision is closed with absorbable suture. No drain is necessary.

### TECHNIQUES

- The proximal aspect of the plate is fixed loosely.
- A subtrochanteric osteotomy is believed to be less hazardous to the hip vascularity than an intertrochanteric osteotomy.
- The femur is shortened by the amount that the cut ends of the femur overlap when the femoral head is reduced (TECH FIG 3D).
- The shortened fragment of femur can be used for holding open a pelvic osteotomy.

- The plate is prebent slightly and is secured with some compression applied.
- The Steinmann pins are used to judge any rotation that is desired.
- If excessive femoral torsion was noted, some of this can be judiciously corrected.
- The tension band effect of the vastus lateralis muscle is restored (TECH FIG 3E).
- The incision is closed with absorbable suture. No drain is necessary.

### TECH FIG 3

- **A.** About 5 mm of the most anterior edge of the gluteus medius muscle is detached from the greater trochanter so that the femoral neck can be palpated and visualized (shown on a left hip). **B.** The vastus lateralis muscle is detached from the trochanteric ridge (TR) and the posterior intermuscular septum (IS) to expose the proximal femur (F). **C.** A one-third tubular plate has been attached to the proximal femur and a 2-cm segment of bone has been removed from the subtrochanteric aspect of the femur. **D.** The femur has been shortened, rotated into less antetorsion, and compressed. **E.** The tension band of the vastus lateralis muscle is re-established with 0 absorbable suture.

### PEARLS AND PITFALLS

#### Diagnosis
- A painful dislocated hip in a newborn or young infant could be a septic dislocation.
- Bilateral hip dislocation may be difficult to determine because the hips may be symmetrically dislocated.
- An adolescent with newly diagnosed hip dysplasia, particularly if bilateral, may have an underlying condition such as Charcot-Marie-Tooth disease.

#### Imaging studies
- Treatment should not be based on a radiology report. The surgeon should personally examine all images.
- An AP pelvis view should be obtained so that the contralateral hip is available for comparison.
- The Shenton line is reliable after age 3 years for indicating subluxation.

#### Nonoperative treatment
- Pavlik harness treatment should not be extended beyond 3 weeks if it is not working.
- A child should be comfortable in a Pavlik harness or a brace. If not, there may be a risk of nerve palsy or osteonecrosis.
- An inadequate closed reduction or a reduction that requires excessive force or extreme position for stability can result in osteonecrosis.

#### Operative treatment
- In the anterior approach, the surgeon should always obtain adequate medial exposure and visualize the entire acetabulum.
- Femoral shortening is necessary for a high dislocation if excessive force is required to bring the femoral head into the joint.
- The acetabular labrum should not be resected.
- The older patient may need a simultaneous acetabular osteotomy for stability or because of excessive acetabular dysplasia.
- Patients older than 8 years with a dislocated hip, particularly those with bilateral dislocation, may have excessive deformity to justify reconstructive surgery.
### Postoperative Care
- A spica cast is applied at the time of surgery.
- A Gore-Tex liner protects the skin from excoriation.
- The cast is removed at 6 weeks.
- A night brace can be used until the acetabulum has remodeled.
- Physical therapy is generally not needed.
- Follow-up radiographs are obtained.
  - The acetabulum will remodel the most in the first year after surgery.
  - If the acetabular shape does not normalize within several years, a pelvic osteotomy is indicated.

### Outcomes
- Patients treated with a Pavlik harness may have persistent acetabular dysplasia in adulthood and should be followed until skeletal maturity.
  - The younger the age at reduction, the better the final Severin grade at maturity. This in turn predicts the need for total hip arthroplasty in later adulthood.
  - About 50% of hips that underwent closed reduction in childhood had residual acetabular dysplasia as adults.
  - The best results occur if there is no osteonecrosis, femoral growth disturbance, or residual subluxation.
  - Persistent acetabular dysplasia, if present past age 7 years, is associated with a poor late outcome. A persistent upsloping sourcil and a centering discrepancy suggest a need for surgical correction in the younger child.
  - Early measurements of the acetabular index (AI) are also predictive for Severin grade at maturity.
  - In particular, an AI of 35 degrees or higher at 5 or more years after reduction has an 80% association with Severin grade III or IV at maturity.

### Complications
- Osteonecrosis
- Late physeal and lateral femoral growth arrest
- Inadequate reduction with persistent subluxation
- Loss of reduction and redislocation
- Stiffness
- Lack of remodeling after reduction
- Infection
- Arthritis

### References
Developmental dislocation of the hip (DDH) occurs in 1.5 babies per 1000 live births. When diagnosed in the newborn period, closed treatment with the Pavlik harness is successful in 95% of dysplastic hips and up to 80% of dislocated hips.

Closed reduction is indicated when Pavlik harness treatment has failed, and when presentation for treatment is delayed past 6 months of age.

Open reduction is reserved for babies in whom closed reduction either is unobtainable or lacks stability, or for those who are diagnosed with a dislocated hip later than 18 to 24 months of age.10

The medial approach for open reduction is used most frequently in the young baby less than 12 to 18 months of age in whom an attempted closed reduction under anesthesia has been unsuccessful.

ANATOMY

Reduction of a dislocated hip is impeded by:
- The iliopsoas tendon, which is tautly stretched across the inferior capsule owing to the displacement of the femoral head
- The inferomedial hip capsule, which becomes constricted
- The transverse acetabular ligament, which spans the inferior aspect of the horseshoe of the acetabulum
- The pulvinar, which is fibrofatty tissue occupying the cavity of the true acetabulum
- The acetabular labrum, which can be infolded and serve as a doorstop blocking a deep and medial reduction
- Anatomic landmarks for the medial approach are as follows:
  - The adductor longus tendon originating on the pubis
  - The pectineus, lying anterior to the adductor brevis (which is deep to the adductor longus)
  - The femoral artery, vein, and nerve, which are located as a bundle anterior to the pectineus muscle
  - The medial femoral circumflex artery, which lies in the interval between the pectineus and the femoral neurovascular bundle and is important for the circulation of the ossific nucleus of the proximal femur

PATHOGENESIS

DDH is more common in female babies and is linked with breech presentation, oligohydramnios, and firstborn children.

DDH is associated with congenital knee hyperextension and may be more likely in babies with torticollis and metatarsus adductus.

A positive family history is present in a minority of babies with DDH and most likely represents familial hyperlaxity.

Idiopathic DDH must be differentiated from the teratologic hip dislocation seen in infants with such disorders as arthrogryposis and Larsen syndrome.

While research has shown that mild dysplasia, seen on ultrasound imaging of the newborn hip, often resolves spontaneously without treatment, the majority of babies with dislocatable or dislocated hips will progress from unstable hips to fixed dislocations in the absence of treatment.

PATIENT HISTORY AND PHYSICAL FINDINGS

The physical examination methods are summarized below. It is very important that the child is relaxed and quiet during the examination.

Limited abduction during range-of-motion testing may signify a dislocation and merits imaging. Abduction can be symmetric in bilateral dislocations.

The patient is examined for the Galeazzi sign. Asymmetry is abnormal and may indicate a hip dislocation or a congenital short femur. The apparent femoral lengths will be equal in bilateral dislocations.

Extra thigh folds may be present in unilateral DDH, but thigh fold asymmetry is often nonspecific.

The child is examined for the Ortolani sign. A positive sign represents the reduction of a dislocated hip. It is usually present in the newborn with DDH but disappears as the dislocation becomes fixed.

A positive Barlow sign represents the ability for a reduced hip to be dislocated because of instability. It disappears as a fixed dislocation develops.

In addition to a complete examination of each hip, the knees, feet, and upper extremities should be examined for contractures to rule out a teratologic dislocation.

The spine should be inspected for signs of dysraphism, which may result in a hip dislocation due to muscle imbalance.

IMAGING AND OTHER DIAGNOSTIC STUDIES

In infants less than 3 months of age, ultrasound of the hip is the preferred imaging study.

The femoral head, acetabulum, and triradiate cartilage can be identified.

The absence of coverage of the femoral head by the bony acetabulum is seen in the dislocated hip, which appears lateralized relative to the pelvis.

The alpha angle, which represents the slope of the bony acetabulum, is decreased (normal is more than 60 degrees), and the beta angle, which represents the cartilaginous acetabulum, is increased (normal is less than 55 degrees) in babies with hip dysplasia and hip dislocation (FIG 1A,B).

In infants 3 months of age and older, an anteroposterior (AP) pelvic radiograph is diagnostic (FIG 1C).

The line of Shenton, drawn along the inferomedial aspect of the proximal femur and the superior aspect of the obturator foramen, is disrupted.
The ossific nucleus may be smaller than the contralateral side, or absent altogether.

The medial proximal femoral metaphysis lies lateral to the Perkins line (drawn vertically from the lateral aspect of the bony acetabulum).

The acetabular index, which is the angle subtended by the Hilgenreiner line (a horizontal line drawn through the triradiate cartilages), and a line drawn along the bony acetabulum, is increased.

A pseudoacetabulum proximal and lateral to the true acetabulum may be present.

DIFFERENTIAL DIAGNOSIS
- Teratologic hip dislocation (ie, arthrogryposis)
- Neuromuscular dislocation (ie, spina bifida)
- Congenital short femur
- Coxa vara

NONOPERATIVE MANAGEMENT
- The Pavlik harness is the treatment of choice for infants with hip dysplasia or instability from birth to age 6 months.
- The Pavlik harness is less successful in patients with fixed dislocations but may be attempted for a period not to exceed 4 weeks, following which a reduction must be documented by either sonogram or radiograph.
- There is no role for nonoperative management of a baby 6 months of age or older with a fixed hip dislocation.

SURGICAL MANAGEMENT
- Surgical management can be delayed in the very young infant until the baby reaches sufficient size for a safe anesthetic and effective cast immobilization. We favor proceeding with surgical reduction (closed or open) at the age of 6 months in the healthy baby.
- The importance of delaying surgery until the presence of ossification within the femoral head remains controversial. While some studies report an increased incidence of avascular necrosis when the ossific nucleus is absent, others report an increased number of surgical procedures in children in whom reduction is delayed. We favor proceeding with reduction rather than waiting for ossification.²

Preoperative Planning
- Traction may be used to increase the likelihood of a successful closed reduction, although current trends in the United States show a declining use of preoperative traction.

Positioning
- The child is positioned supine on a radiolucent operating table.
- The perineum is isolated with adhesive tape.
- Surgical drapes are sutured in place to allow free movement of the extremity.
- Towel clips should be avoided around the groin as they interfere with fluoroscopic visualization of the hip.

Approach
- The medial approach to the dislocated hip is best suited to infants less than 12 months of age, but it has been used by other authors successfully in infants up to 24 months of age.
- The medial approach described by Ludloff³ accesses the hip in the interval between the pectineus and the adductor brevis.
- We favor the approach described by Weinstein,⁸,⁹ which exposes the hip between the femoral neurovascular bundle anteriorly and the pectineus muscle posteriorly. This interval allows for more direct visualization of the hip capsule and the medial femoral circumflex artery.

INCISION AND INITIAL DISSECTION
- With the hip flexed and abducted, a transverse incision is made just lateral to the groin crease, centered over the palpable adductor longus tendon (TECH FIG 1A).
- The fascia overlying the adductor musculature is opened (TECH FIG 1B).
- The adductor longus tendon is isolated and divided (TECH FIG 1C). The tendon can be dissected free from the underlying adductor brevis with two blunt retractors.

The adductor brevis is identified with its overlying anterior branch of the obturator nerve. The pectineus is located anterior to the adductor brevis (TECH FIG 1D). Blunt retractors are used to identify the superior border of the pectineus.
DEEP DISSECTION

- The femoral vessels are retracted gently anteriorly, and the pectineus muscle is retracted posteriorly (TECH FIG 2A).
- The iliopsoas tendon can be identified. The surgeon can rotate the hip and feel the insertion site on the small prominence of the lesser trochanter. The psoas tendon is isolated and divided (TECH FIG 2B).
- The surgeon carefully identifies the medial femoral circumflex artery as it traverses superior to inferior on the capsule of the hip. If possible, a small vessel loop is passed around the vessel to protect it. Otherwise, visualization of the vessel is maintained throughout the procedure.
- The femoral head is palpated beneath the medial femoral circumflex artery. Kidners are used to bluntly expose the hip capsule (TECH FIG 2C).

CAPSULOTOMY AND ACETABULAR EXPOSURE

- The capsule is incised along the rim of the acetabulum using a scalpel.
- The white glistening cartilaginous femoral head is visualized (TECH FIG 3A). The hip is rotated to identify the ligamentum teres insertion on the superior aspect of the femoral head (TECH FIG 3B), and it is released (TECH FIG 3C).
- The stump of the ligamentum is traced into the true acetabulum (TECH FIG 3D).
The incision in the capsule is completed to gain access to the acetabulum.

- The ligamentum teres is excised from the floor of the acetabulum using scissors.
- With a pituitary rongeur, the fibrofatty pulvinar is removed from the acetabulum. The surgeon should take care to preserve the underlying articular cartilage of the acetabulum (TECH FIG 3E).

- The release of the acetabulum is completed by releasing (with scissors) the transverse acetabular ligament at the base of the acetabulum.
- The surgeon should not excise or incise the acetabular labrum: it is an important growth center of the acetabulum and should be preserved.

HIP REDUCTION, CAPSULORRHAPHY, AND CLOSURE

- The hip is reduced under visualization by abducting the hip and lifting the greater trochanter anteriorly (the Ortolani maneuver). The hip should reduce readily and be quite stable in flexion. It will dislocate posteriorly with adduction. The reduced hip will appear relatively superficial, and the femoral head will be visible in the wound.

- The reduction should be verified fluoroscopically at this point. If it is difficult to assess the reduction because of absence of ossification of the femoral head, a small drop of contrast can be placed in the acetabulum.

- If the hip cannot be reduced, or if the reduction requires undue force to pull the hip into the acetabulum, the surgeon should recheck the capsular release and the transverse acetabular ligament.

- In rare instances, the hip cannot be gently reduced and femoral shortening through a separate lateral approach is required. In infants less than 1 year of age who are otherwise normal, this is generally not necessary.

- From this point onward, the hip must remain flexed to 90 degrees and gently abducted to maintain reduction. An assistant should be assigned to observe the position of the hip.

- The vessel loop is removed from the medial femoral circumflex artery, which has been protected throughout the operation.

- The subcutaneous layer and skin are closed. A drain is not necessary.

- The wound is dressed and an occlusive bandage applied to deter contamination from diaper contents.
CASTING

- The child is transferred to an infant spica table, and a double spica cast is applied with the hips flexed 90 degrees and gently abducted no greater than 60 degrees (TECH FIG 4A).
- The surgeon should take care to cover the posterior aspects of the buttocks and mold beneath the greater trochanters to prevent “falling through” the spica posteriorly (TECH FIG 4B).

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>Unstable closed reduction or fixed dislocation in an infant less than 1 year of age. The procedure is still possible to age 2 years.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Surgical technique</td>
<td>Drapes are sewn to avoid inability to see the hip on C-arm fluoroscopy. The ligamentum teres is used to find the acetabulum. The medial femoral circumflex artery is always protected. A lighted suction can be invaluable in improving visualization in the small incision. If the reduction cannot be assessed easily, a small drop of contrast can be added in the acetabulum, and then the hip is reduced. The surgeon should never force a reduction; avascular necrosis may result.</td>
</tr>
<tr>
<td>Postoperative care</td>
<td>The reduction is assessed with either radiographs or CT once the child is awake. A limited CT scan of the hip allows accurate assessment. If the hip is dislocated, the cast is removed at once.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- A radiograph is taken before waking the child from anesthesia to document the reduced hip within the spica cast (FIG 2A).
- A limited CT scan may be performed within 24 hours after surgery to visualize the reduced hip after the child moves about in the cast (FIG 2B).
- The cast is changed under anesthesia in 6 weeks and the hip is examined fluoroscopically. At this time, a one-and-a-half spica can be applied.
- On occasion, a third spica will be needed, to be worn between 12 and 18 weeks after medial open reduction.
- Bracing with an abduction orthosis after cast removal is prescribed at the discretion of the surgeon.
Periodic radiographs are needed to monitor the growth of the ossific nucleus and the resolution of acetabular dysplasia.

OUTCOMES
- A satisfactory outcome after medial open reduction of the infant’s hip can be expected in about 75% of children. Reduction can be universally achieved, and redislocation after a medial open reduction is rare. Owing to the limited dissection, prolonged postoperative stiffness is a rare event.
- When an adverse outcome occurs after medial open reduction, it usually is related to the diagnosis of postoperative avascular necrosis or residual acetabular dysplasia.

Avascular Necrosis
- Avascular necrosis has been documented in 9% to 43% of hips after medial open reduction. The large discrepancy in rates between series is due to differing criteria for its diagnosis and variation in the length of follow-up.
- The severity of avascular necrosis varies widely between hips that have temporary irregular ossification of the epiphysis (Bucholz-Ogden type I) to complete avascular necrosis with an aspherical femoral head and coxa breva (type IV).
- The presence of type I avascular necrosis does not preclude a successful outcome at skeletal maturity, while whole-head avascular necrosis dooms the hip to a poor outcome and leg-length discrepancy despite multiple surgical procedures.
- Many series do not include the hips with irregular ossification, so it is imperative when comparing complication rates to ascertain which hips were included in the group with postoperative avascular necrosis. Although the published series of medial open reductions vary in the likelihood of avascular necrosis, it is clear that the proximity of the medial femoral circumflex artery to the medial hip capsule places the hip at greater risk for avascular necrosis during this approach compared to the anterior open reduction.
- Because of variation between series in length of follow-up, the rate of type II avascular necrosis ranges widely. Typically, type II avascular necrosis becomes apparent in late childhood and early adolescence, when the proximal femur seems to grow into valgus because of a lateral physal growth disturbance.
- In series with short-term follow-up, the rate of type II avascular necrosis may be lower than in those where skeletal maturity is achieved. Review of the DDH literature shows that type II avascular necrosis is not specific to the medial approach to the hip, however, as it may also be seen after anterior open reduction, and even closed reduction.

Acetabular Dysplasia
- Persistent acetabular dysplasia may be seen after medial open reduction of the hip. This approach does not facilitate concomitant pelvic osteotomy, unlike the anterior open reduction, in which the iliac crest is exposed. Yet the optimal age for the medial open reduction (age 1 year or less) is young enough that the surgeon can expect the majority of patients to experience resolution of their dysplasia with growth.
- Mankey et al found that one third of babies treated with medial approach open reduction required subsequent pelvic osteotomy for residual acetabular dysplasia.

COMPICATIONS
- Redislocation
- Avascular necrosis
- Infection
- Need for future pelvic osteotomy due to persistent acetabular dysplasia

REFERENCES
DEFINITION
- Septic arthritis of the hip affects children of all ages, from the newborn to adolescents. The principles of treatment include early and accurate diagnosis, prompt surgical drainage, appropriate antibiotic coverage, and judicial management of late sequelae. The worse outcomes occur when there has been a marked delay in the diagnosis.

ANATOMY
- Synovial membrane with its rich blood supply lines the joint capsule.
- Blood supply to the hip is from the medial and lateral femoral circumflex vessels (FIG 1).
- Intra-articular retinacular vessels travel up the femoral neck and enter the femoral head. These vessels do not cross within the proximal femoral physis.
- Because the proximal femur is an intra-articular metaphysis, primary femoral osteomyelitis in this location can decompress into the hip joint.
- Many muscles that are in close proximity to the hip joint, including iliopsoas, piriformis, and obturator internus and externus, may develop pyomyositis or an abscess; this can mimic septic hip arthritis.

PATHOGENESIS
- Bacteria can enter the hip joint cavity directly via the hematogenous route to the subsynovial layer of the capsule or indirectly from the proximal femoral metaphysis and occasionally from adjacent acetabular infection.
- Polymorphonuclear cells enter the joint cavity with plasma proteins and inflammatory fluid.
- The resulting tense effusion can increase intracapsular pressure.
- Articular cartilage destruction occurs from proteolytic enzyme degradation from cells of the synovial membrane and from interleukin-1 from monocytes, which releases proteases by chondrocytes and synoviocytes.
- Animal studies show that proteoglycan matrix can be lost by 5 days and collagen by 9 days after an infection starts. Antibiotics do not completely prevent this degradation if treatment is delayed.

NATURAL HISTORY
- Although most patients have excellent outcomes, the hip joint accounts for about 75% of published reports of poor outcome from septic arthritis.

FIG 1 • A. Anterior hip vascularity. The medial and somewhat the lateral femoral circumflex vessels from the deep femoral artery supply the vascularity to the femoral head. B. Posterior hip vascularity. Intracapsular retinacular vessels from the medial circumflex vessel pierce through the capsule and travel up the posterior femoral neck.
Poor results occur more frequently in infants less than 6 months of age, if there is a delay in treatment of greater than 4 days, and with associated proximal femur osteomyelitis and infection with *Staphylococcus aureus*. The most severe sequelae are more often seen in newborns and infants.

A frequent scenario when there is a poor outcome is the failure to make the diagnosis of septic hip arthritis, either from not recognizing the serious nature of the condition or failure to promptly perform adequate surgical drainage and administer appropriate intravenous antibiotics.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The history should include a detailed timeline of events leading up to presentation.
- In the most recent prospective studies evaluating clinical predictors for septic hip arthritis, a fever above 38.5°C was the strongest predictor.
- The severity of pain, particularly pain at rest and night pain, indicates inflammation.
- Associated illnesses and infections, history of trauma to the hip, recent dental procedures, and underlying medical conditions or steroid use may lead to infection in a susceptible host.
- The clinician should always ask about recent antibiotic treatment, since this may mask many of the findings of septic hip arthritis and change the threshold for obtaining imaging studies and for performing hip aspiration.
- The clinician should conduct a visual inspection with the child lying supine on the table, noting whether the hip is in abduction, flexion, and external rotation (FIG 2).
  - The hip joint assumes a position of least intracapsular pressure.
  - The clinician should inspect for skin rash, erythema, warmth, swelling, and tenderness over overlying muscles and the hip joint.
  - The clinician should palpate the pelvis and lower extremities for local swelling and tenderness.
  - The clinician should examine the child walking. Antalgic limp indicates that the patient is unable to spend much time weight-bearing on the hip joint. The child may have mild pain early or the pain may be so severe that the patient is unable to walk.
  - The clinician should observe the hip range of motion. Gradually, there is limited ability to move the hip joint as inflammation and pressure of the hip joint increase. Pain with hip extension and internal rotation suggests involvement of the psoas muscle.

- The clinician should inspect and palpate the spine. Septic discitis in a young child can present as refusal to walk and can resemble septic hip arthritis.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging and laboratory studies selected are determined by the clinical evaluation, probability of the findings being septic hip arthritis, and need to exclude other conditions.
- Plain radiographs (FIG 3A)
  - Key features include hip abduction, increased soft tissue density, widened medial joint space, osteopenia if the infection is longstanding, and femoral or acetabular osteolytic lesions.
  - A particularly worrisome finding in the neonate is a painful dislocated hip (FIG 3B). Bone lesions and destruction are typically delayed 1 to 2 weeks.
- Ultrasound imaging (FIG 3C) is performed bilaterally, with images obtained along the axis of the anterior femoral neck. This is very specific for detecting intra-articular fluid in the hip.
- Because the pelvis is deep and difficult to examine, MRI is an extremely useful imaging modality to examine the tissues surrounding the hip joint or within the pelvis (FIG 3D–F).

---

**FIG 2** Right hip is held in flexion, abduction, and external rotation.

**FIG 3** Diagnostic imaging. A, B. AP radiographs. A. The right hip is held in abduction with increased soft tissue density and slight lateral displacement of the femoral head. B. Left hip of an infant showing acute displacement from septic hip arthritis. The left proximal femur is laterally displaced compared with the right. (continued)
Femoral head is midway between anterosuperior iliac spine and center of pubis symphysis and about 2 cm distal to midway point.

**Adductor longus**

**Needle inserted just posterior to adductor longus**

**Pubis symphysis**

**FIG 3 (continued)**

**C.** Ultrasound imaging of hip along axis of the femoral neck. The distance between the femoral neck and head is shown by the red line. There is increased intracapsular fluid. **D–F.** MRIs in an 11-year-old boy with fever and pain with internal rotation of the hip. He was limping but able to walk. Erythrocyte sedimentation rate was 50 mm/hr and C-reactive protein level was 5.8 mg/L. The radiograph was normal. **D.** T1-weighted coronal image of pelvis. There is an abscess (*) within the obturator internus muscle. **E.** T2-weighted coronal image of pelvis. The abscess (*) is more apparent, as is the involvement of the acetabulum (solid dot) and small hip joint effusion (dashed outline). **F.** T1-weighted coronal image with gadolinium for enhancement. Cavitary nature of the abscess (*) is even more apparent. Patient underwent percutaneous interventional radiology catheter drainage on two occasions and received intravenous antibiotics for treatment of this methicillin-sensitive *Staphylococcus aureus* infection. **G,H.** Hip aspiration. **G.** Aspiration of right hip through adductor approach. The large-bore needle is inserted just posterior to the adductor longus and is directed toward the femoral head. **H.** Fluoroscopy image of needle tip at the junction of the femoral head and proximal femoral metaphysis. (A: From Sucato DJ, Schwend RM, Gillespie R. Septic arthritis of the hip in children. J Am Acad Orthop Surg 1997;5:249–260. D–F: Courtesy of Mark Sinclair, MD, Children's Mercy Hospital, Kansas City, MO.)
NONOPERATIVE MANAGEMENT

Surgical treatment is indicated when septic hip arthritis has been confirmed.

Nonoperative management is an adjuvant to surgery and includes making an early and specific bacterial diagnosis, administering the correct intravenous antibiotic and dose, and adjusting the antibiotic coverage based on culture and sensitivity results.

Intravenous antibiotics are converted to oral when the child is clearly recovering (feels well, afebrile, able to walk, minimal pain with hip range of motion, and improving laboratory studies). The duration of antibiotic treatment is generally shorter than for osteomyelitis and depends on the severity of infection and the virulence of the organism.

A peripherally inserted central catheter is used if intravenous antibiotics will be given for several weeks. An infectious disease consultation is helpful for cases with an unusual organism, unusual host, or unusual site of infection.

SURGICAL MANAGEMENT

Confirmed septic hip arthritis is a surgical emergency and the hip should be drained without excessive delay.

If the joint aspiration is performed in the operating room, the arthrotomy can be performed in the same setting.

The principles of surgical intervention include open arthrotomy, irrigation of purulence, and débridement of dead tissue.

Preoperative Planning

Radiolucent table
An aspiration of the hip is performed before an arthrotomy if the diagnosis is not clear. In children, the hip joint is aspirated with a spinal needle inserted just posterior to the adductor longus tendon and directed toward the femoral head (FIG 3G,H).

Positioning
Lateral or semilateral position with hip and lower extremity draped free (FIG 4).

Approach
There are several approaches to draining the pediatric hip, including medial, direct anterior, anterior through a modified Smith-Peterson approach, anterolateral, and posterior.

The posterior approach is not recommended because of the femoral head vascularity and potential for posterior hip instability.

DIFFERENTIAL DIAGNOSIS

Transient synovitis
Trauma
Pelvic or proximal femur osteomyelitis
Pyomyositis of the adductors, hamstrings, obturator muscles, or piriformis muscles
Langerhans cell histiocytosis
Leukemia, Ewing sarcoma, metastatic neuroblastoma
Other forms of arthritis, including Lyme disease, tuberculosis, fungal or chronic childhood arthritis
Iliopsoas or iliacus abscess
 Appendicitis or ovarian cyst
Child abuse
Osteonecrosis of the femoral head and sickle cell disease
MODIFIED SMITH-PETERSON ANTERIOR APPROACH

- The entire hip and lower extremity is draped free so that the hip joint can be moved through a full range of motion.
- The incision is a modification of the classic Smith-Peterson approach with a cosmetic and limited incision in the groin, centered just below the anterior superior iliac spine (ASIS) (TECH FIG 1A).
- Sharp knife dissection is used to the deep fascia. The incision is continued until no more fat is apparent and the deep fascia is exposed.
- A sponge is used to separate the distal flap from the deep fascia.
- There is a small interval of fat between the tensor and sartorius muscles several centimeters distal to the ASIS (TECH FIG 1B). The surgeon should incise slightly lateral to the fat on the fascia of the tensor.
- Army-Navy retractors are used to separate this internerous interval until the rectus femoris muscle is visualized.
- A Kidner Sponge is used on the lateral edge of the rectus femoris muscle, and the surgeon dissects along this edge proximally until the reflected head of the rectus femoris muscle is exposed (TECH FIG 1C).
- Just lateral to the reflected head is the hip capsule, which is covered with fat.
- The fat is reflected to expose the hip capsule. The reflected head of the rectus femoris muscle may be divided for better exposure of the hip capsule.
- It is best to visualize a large area of the hip capsule for better orientation before making an incision into it.
- The capsule is incised with a no. 15 blade.
- A 3-mm 45-degree Kerrison rongeur is useful to remove several millimeters of the anterior capsule for continued postoperative decompression (TECH FIG 1D).
- The joint is irrigated with saline through a large-bore intravenous catheter placed deep within the joint.
- A suction drain is placed for several days after surgery until there is only minimal drainage.
- The skin is closed loosely with interrupted nylon sutures to allow potential drainage.
- Closing the deep fascia increases the risk of reaccumulation.

TECH FIG 1 • Modified Smith-Peterson anterior approach to the right hip. A. The incision is placed in the anterior groin crease for best cosmesis. B. The tensor–sartorius muscle interval is identified distally where the muscles begin to separate. (continued)
DIRECT ANTERIOR APPROACH

- The direct anterior approach is especially useful when there is infection in the iliopsoas bursa, which needs to be opened along with the hip joint.
  - This is also a direct approach for dividing the psoas tendon over the pelvic brim for a tight tendon, as seen in cerebral palsy, or a snapping hip related to the iliopsoas tendon.
  - It uses a similar incision as the anterior approach, placed just below the ASIS but centered more medially, between the femoral neurovascular bundle and the ASIS.
- Sharp dissection continues to the deep fascia until no further superficial fat is identified.
- A sponge separates both flaps off the deep fascia.
- The medial border of the sartorius muscle is identified. Just medial and slightly deeper is the fascia of the iliacus muscle, which is opened (TECH FIG 2A).
- The femoral nerve is identified, reflected medially, and protected (TECH FIG 2B). This provides assurance that the femoral artery and vein, which lie medial to the femoral nerve, are out of the field.
- The dissection is continued along the medial border of the iliacus muscle until the iliopectineus eminence of the pubic bone is identified.
- Deep to the iliacus muscle is the large bursa of the iliopsoas (TECH FIG 2C). This is opened and the psoas tendon is isolated proximally and distally.
- Deep and lateral to the psoas tendon is the hip capsule.
  - A small elevator is used to visualize the surface of the capsule before entering it with a no. 15 blade.
- A 3-mm 45-degree Kerrison rongeur is used to enlarge the capsulotomy.
  - The joint is irrigated and a suction drain placed. If this approach is used for infection, the surgeon should not close the deep fascia.
ANTERIOR LATERAL APPROACH

- A straight longitudinal incision centered over the greater trochanter is used.
- The tensor fascia is divided longitudinally in line with the skin incision.
- The interval between the most anterior border of the gluteus medius muscle as it attaches to the greater trochanter and the proximal aspect of the vastus lateralis muscle is identified (TECH FIG 3A).
- Several millimeters of the gluteus medius attachment to the greater trochanter is released. This allows the examiner to palpate the anterior aspect of the femoral neck, up to the level of the femoral head.
- The gluteus medius muscle is retracted proximally and an incision is made in the anterior capsule (TECH FIG 3B). It can be enlarged with the Kerrison rongeur.
- After irrigation and débridement, a drain is left in the hip joint for several days.
- The skin is closed with several interrupted nylon sutures, but the deep fascia should not be closed.

TECH FIG 3 • A. The most anterior fibers of the gluteus medius muscle are divided (dashed line) as they insert on the vastus lateralis and greater trochanter. B. The gluteus medius muscle is retracted and the anterior capsule is palpated and visualized.
POSTOPERATIVE CARE

- A surgical drain is used for several days. It is removed when it is no longer functioning.
- The family needs to understand that repeat drainage is a possibility should symptoms recur or if improvement is inadequate.
- A spica cast is frequently used if the radiograph shows laxity and lateral displacement, especially in the infant.
- Another radiograph is obtained when the antibiotics are discontinued to be sure there is no evidence of osteomyelitis.
- Another radiograph is obtained at 4 to 6 months to document adequate physeal growth.
- In a growing child with a septic joint, the parents should be informed that growth of the bones in that area can be affected.

OUTCOMES

- In reports of poor results from septic arthritis, 75% involve the hip joint.
- Severe sequelae with a destroyed femoral head are most commonly seen in newborns and infants and are often related to a delay in diagnosis and treatment (**FIG 5**).
- Infants in particular should be followed for several years to document adequate development of the hip joint.
- Simple late reconstruction should focus on maintaining pain-free hip range of motion, realignment procedures if there is a reasonably formed femoral head, and simple procedures to achieve comparable limb lengths.2
- Complex late reconstruction should rarely be used unless the functional goal can clearly be stated and the procedure has a reasonable chance of meeting that goal.

COMPLICATIONS

- Avascular necrosis of the hips can lead to complete destruction of the femoral head (**FIG 6**).
- Septic hip dislocation
- Complete separation of the proximal femoral epiphysis
- Proximal femur growth arrest and limb-length discrepancy9
- Closure of the triradiate cartilage
- Late arthritis
REFERENCES

DEFINITION

- The Salter innominate osteotomy is commonly performed in conjunction with an open reduction for the dislocated hip in developmental dysplasia of the hip (DDH).
- The osteotomy can also be performed to treat acetabular dysplasia in the child with a concentrically reduced hip.7

ANATOMY

- The Salter innominate osteotomy rotates around an axis running from the posterior cortex of the sciatic notch to the midpoint of the symphysis pubis.
- The osteotomy rotates the acetabulum to improve anterior and lateral femoral head coverage.
- The distal fragment of the osteotomy undergoes slight distal, posterior, and medial displacement in addition to rotation.5
- An up-to-30-degree bone wedge inserted in the osteotomy site increases anterior and lateral femoral head coverage in a proportion of about 2:1 (the practical limit of correction).5

PATHOGENESIS

- Acetabular dysplasia is caused by the following:
  - Lack of a reduced, spherical head within the growing acetabulum
  - Abnormal interstitial or appositional growth within the acetabular and triradiate cartilage
  - Abnormal development of the secondary centers of ossification of the ilium, pubis, and ischium
  - In the developmentally dislocated hip, the acetabular labrum is flattened and hypertrophied, referred to as the "neolimbus."
  - The acetabular dysplasia in the infant and young child with DDH is predominantly anterior and lateral.8

NATURAL HISTORY

- The natural history of the dysplastic hip with hip subluxation is worse than the hip with acetabular dysplasia alone.
  - Patients with subluxated dysplastic hips develop pain and disability and radiographic evidence of osteoarthrosis. The age of onset of symptoms depends on the degree of subluxation, with severe subluxation leading to symptoms in the third decade of life.10
  - Patients with acetabular dysplasia without subluxation develop radiographic evidence of osteoarthrosis in the sixth decade of life, and some will develop pain and disability, depending on the degree of dysplasia.10

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with developmental hip dislocation may have a positive family history and are usually female and first-born children.
- There can be a history of breech presentation at birth.
- Children with a dislocated hip usually meet their gross motor milestones within the appropriate timeframe.
- The pertinent physical examination findings in the walking child (the timeframe when this operation is typically performed) are listed below.
  - Hamstring tightness test: Normally, the hamstrings will tighten with passive knee extension, and no knee hyperextension should be possible. A positive test implies hip dislocation or flaccid paralysis of the hamstring muscles.
  - Gluteus medius lurch: Trunk lean over the stance phase leg signifies a positive test, which is a nonspecific sign of hip pathology caused by dislocation, coxa vara, or painful hip conditions.
  - Galeazzi sign: Knees at different levels signify a positive test, which indicates hip dislocation or congenital shortening of the femur.
  - Trendelenburg sign: If the pelvis dips away from the affected leg during single limb stance, the test is positive. Like the gluteus medius lurch, a positive test is a nonspecific sign of hip pathology caused by dislocation, coxa vara, or painful hip conditions.
  - Inspection of inguinal skin fold: Normal inguinal skin folds are symmetric and stop short of the anal aperture posteriorly. Asymmetric skin folds are a relatively nonspecific finding in the dislocated hip.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Standing anteroposterior (AP) and supine frog-leg lateral pelvis radiographs
  - On the AP film, the acetabular index should be measured to diagnose acetabular dysplasia. Normal values are 35 degrees at birth, 25 degrees at 1 year of age, and 20 degrees at 2 years of age (FIG 1).9
  - Also on the AP film, the line of Shenton is inspected for discontinuity, which represents hip subluxation (FIG 1).
  - A false-profile view of the hip can identify more subtle cases of acetabular dysplasia, particularly in the walking child.
  - Advanced imaging studies (3D CT scanning of the acetabulum, MRI of the hip) may be of value in older children to assess acetabular morphology.

DIFFERENTIAL DIAGNOSIS

- Proximal femoral focal deficiency
- Congenitally short femur
- Developmental coxa vara
- Legg-Calvé-Perthes disease
**NONOPERATIVE MANAGEMENT**

- The acetabular index should be observed for improvement over 12–18 months after successful closed reduction in the child less than 18 months of age.
  - If residual acetabular dysplasia exists, a Salter innominate osteotomy can be performed at that time.²
  - Whether the osteotomy should be performed concurrently with an open reduction or as a staged procedure is controversial.
  - A child less than 18 months old who fails closed reduction can be treated with an isolated open reduction of a dislocated hip and observed for improvement in the acetabular index into the normal range over 12 to 18 months.
  - A subsequent Salter innominate osteotomy should be performed if acetabular development is deficient after observation.⁴

**SURGICAL MANAGEMENT**

- Surgical indications:
  - Age 18 months to 6 years⁶
  - Concentric hip reduction (either preoperatively or intraoperatively with an open reduction)⁵
  - No or minimal osteoarthrosis of the hip
  - At least 100 degrees of hip flexion and 30 degrees of hip abduction
  - Anterior and lateral acetabular dysplasia

**Preoperative Planning**

- A hip arthrogram is first performed in cases of hip dysplasia before patient positioning to confirm a concentric reduction.
  - If there is not a concentric reduction, other procedures (open reduction, proximal femoral osteotomy) are performed to achieve a concentric reduction before performing a Salter innominate osteotomy.
  - For the dislocated hip, a closed reduction is attempted.
  - If a gentle concentric closed reduction is achieved and the patient is over 18 months old, a Salter innominate osteotomy including intramuscular psoas lengthening without open hip reduction can be performed.
  - An estimation of femoral anteversion with fluoroscopy before patient positioning is used to decide if a concurrent femoral derotational osteotomy is necessary.
  - We perform a femoral derotational osteotomy if femoral anteversion is greater than 45 degrees.

**Positioning**

- The patient is placed supine on the operating table with a gel roll under the thoracolumbar spine on the affected side (but not under the affected pelvis), raising the affected side into an oblique position.
- The hip is prepared from the midline anterior and posterior, to the inferior rib cage proximally, and the entire extremity distally (FIG 2).

**Approach**

- An anterior Smith-Peterson approach to the hip is used, with the incision modified as described in Chapter PE-67 (FIG 3).
EXPOSURE OF THE ANTERIOR HIP AND ILIUM

- The exposure of the anterior hip is the same as for an open reduction of the hip in Chapter PE-67.
- While retracting the external oblique muscle proximal and medial, the iliac apophysis is split with a no. 15 blade scalpel from the iliac tubercle to the anterior inferior iliac spine (AIIS).
- The inner and outer tables of the ilium are subperiosteally dissected with Crego periosteal elevators to the sciatic notch.
- An intramuscular psoas tendon lengthening is performed at the pelvic brim.

SALTER INNOMINATE OSTEOTOMY

- Curved Crego or Rang retractors are placed subperiosteally in the sciatic notch from the medial and lateral sides.
- The medial retractor is placed on top of the lateral retractor in the notch.
- The tip of a right-angled clamp is placed on top of the retractors from the medial side of the sciatic notch.
- The Gigli saw is placed into the right angle clamp laterally and pulled around the sciatic notch (TECH FIG 1A).
- The right-angled clamp is rotated into the notch on top of the medial retractor.
- The operating room table is lowered, and with hands as wide as possible, the Gigli saw is used to make the osteotomy, exiting just above the AIIS (TECH FIG 1B).

HARVESTING BONE GRAFT

- The iliac wing is removed with an oscillating saw laterally or bone-biting forceps from the AIIS to the iliac tubercle (TECH FIG 2A,B).
- The graft is shaped in to a 30-degree bone wedge (TECH FIG 2C).
PLACING THE GRAFT

- Towel clamps are used to stabilize the proximal fragment and hinge the distal fragment anterior and lateral. The distal fragment is pulled anteriorly to prevent posterior slipping, and the posterior part of the osteotomy is kept apposed (TECH FIG 3A).
- If done as an isolated procedure, opening the osteotomy site can be facilitated by placing the leg in the figure 4 position.
- The graft is placed in the osteotomy gap concave side medial, with the medial cortex flush with the medial cortex of the proximal and distal fragments (TECH FIG 3B).
- The graft is secured with two threaded Steinmann pins placed from proximal across the graft into the medial and posterior portion of the distal fragment up to the triradiate cartilage (TECH FIG 3C).
- The acetabulum is palpated (if done with an open reduction) or the hip taken through full range of motion (if done as an isolated procedure) to ensure pins are extra-articular.
- An intraoperative obturator oblique radiograph is taken with the pins in place to ensure they do not enter the triradiate cartilage (TECH FIG 3D).

WOUND CLOSURE

- The iliac apophysis is closed with absorbable suture in a figure 8 fashion. The first loop of the figure 8 is circumferential around the entire apophysis, and the second loop captures only the superficial half of the apophysis.
- The pins are cut above the apophysis, coming to lie in the subcutaneous fat, for easy future removal.
- The common head of the rectus femoris tendon is repaired to its insertion.
- Subcutaneous tissue and skin are closed in the standard fashion.
POSTOPERATIVE CARE
- The patient is placed in a one-and-a-half hip spica cast with the affected hip in the position of maximal hip stability and, if possible, close to the position of weight bearing (about 30 degrees of flexion, 20 degrees of abduction, and 20 degrees of internal rotation).
- When performed as an isolated procedure, young children should be immobilized in a single-leg spica cast for about 6 weeks, when early radiographic evidence of healing is evident.
- Older children who are reliable may be allowed to use crutches and perform touch-down weight bearing on the affected side without the use of a single-leg spica cast.

OUTCOMES
- Patients with concentrically reduced hips and corrected acetabular dysplasia with a Salter innominate osteotomy, in the absence of avascular necrosis, have good to excellent functional outcomes scores at over 30 years after the index procedure.
- Functional outcomes are best when the acetabular dysplasia is initially corrected to near-normal radiographic values.1,4

COMPLICATIONS
- Neurovascular injury to structures in the sciatic notch
- Lateral femoral cutaneous nerve injury during surgical exposure
- Inadequate correction of acetabular dysplasia due to inadequate patient selection preoperatively or inadequate acetabular rotation intraoperatively3
- Injury to the femoral nerve due to prolonged retraction of the psoas muscle or incorrect identification of the psoas tendon during intramuscular tenotomy
- Pin penetration into the hip joint or triradiate cartilage
- Nonunion at the osteotomy site
- Migration of the graft due to inadequate fixation3
- Avascular necrosis of the femoral epiphysis3
- Growth arrest of the triradiate cartilage
REFERENCES

DEFINITION
■ The Pemberton (FIG 1A–C) and Dega (FIG 1D–F) osteotomies are performed for acetabular dysplasia that is either part of a developmental disorder or an acquired disorder due to muscle imbalance in neuromuscular conditions.
■ These are reshaping procedures that alter the shape of the acetabulum and increase its volume.7,12
■ They are used primarily to increase anterior acetabular coverage but can be altered to provide more lateral coverage.

ANATOMY
■ The acetabulum develops at the confluence of the growth centers of the ilium, ischium, and pubis.

PATHOGENESIS
■ Normal growth of the acetabulum requires not only that all of these growth centers remain open and function normally but also that the femoral head remains concentrically reduced and stable within the acetabulum.
■ If the growth centers are damaged, either from pathologic conditions or iatrogenically, or if the femoral head is not stable within the acetabulum, normal growth is unlikely to occur and hip dysplasia develops.

FIG 1 • A–C. Pemberton osteotomy depicted on a bone model viewed from anteriorly (A), from inside the pelvis medially (B), and from outside the pelvis laterally (C). The osteotomy starts at the anterioinferior iliac spine (AIIS) and extends posteriorly following the insertion of the capsule. It then turns caudally and bisects the posterior column to the level of the triradiate cartilage. D–F. Dega osteotomy depicted on bone model viewed from anteriorly (D), from inside the pelvis medially (E), and from outside the pelvis laterally (F). As for the Pemberton, the Dega osteotomy starts at the AIIS and extends posteriorly following the insertion of the capsule. However, it then stops about 1 cm from the sciatic notch on the lateral surface. The medial surface is cut just above the horizontal limb of the triradiate cartilage. The more of the medial surface that is left intact, the more lateral coverage the osteotomy provides.
Even with a concentric reduction of the femoral head, the prior period of abnormal growth may prevent the acetabulum from achieving a normal configuration at maturity. The older the child is at the time of reduction, the more likely an osteotomy will be necessary.

**NATURAL HISTORY**

- Many patients with acetabular dysplasia develop subluxation or dislocation of the femoral head. This can lead to early arthritis in the middle adult years.
- The degree of subluxation does not necessarily correlate with the time to onset of symptoms or the degree of arthritic changes.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Hip dysplasia can be diagnosed clinically in newborns and young infants owing to instability of the hip.
- Patients with a history of hip dysplasia are typically followed radiographically until adulthood to ensure normal acetabular development.
- Older children without a prior history of developmental hip dysplasia are typically diagnosed with radiographs based on clinical suspicion, especially when significant risk factors are present.
- Risk factors include breec position, female, first-born, and oligohydramnios. Developmental hip dysplasia is associated with other “packaging disorders.”
- Patients sometimes present in childhood with a limp, hip pain, limb-length discrepancy, or asymmetric hip abduction, particularly those with underlying neuromuscular conditions.
- Routine screening for hip dysplasia in neuromuscular conditions with radiographs is widely performed.
- Examinations and tests to perform include:
  - Ortolani test: Positive if a clunk is felt as a dislocated hip reduces.
  - Barlow test: Positive if a clunk is felt as a reduced hip dislocates.
  - Hip abduction: In a normal hip, abduction should be more than 60 degrees and symmetric. This may be the only abnormal sign in infants. A difference of 10 degrees or more is significant.
  - Galeazzi sign: A difference in thigh length is a positive result. A positive Galeazzi sign can indicate a dislocated hip, a short femur, or a congenital hip deformity.
  - Abnormal skin folds can occur in normal children but may also indicate asymmetric hip abduction.
  - Limp with ambulation, Trendelenburg sign, or limp associated with limb-length discrepancy may be the only abnormal sign in older children.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Dynamic hip ultrasound can be used to detect hip dysplasia in very young infants (under 6 months of age).
- Plain radiographs, including an anteroposterior (AP) view of the pelvis and false profile views, typically can be used to make the diagnosis in older children.
- Radiographic parameters, including the acetabular index, lateral center-edge angle, anterior center-edge angle, the position of the sourcil, and the line of Shenton, should be evaluated (FIG 2).

**DIFFERENTIAL DIAGNOSIS**

- Dislocation is detected by lack of contact between the acetabulum and femoral head.
- Subluxation is detected by a break in the line of Shenton.
- Acetabular dysplasia can be detected by a decrease in the lateral center-edge angle or an increased acetabular index on the AP pelvic radiograph or a decrease in the anterior center-edge angle on the false profile view.
- A pelvic radiograph with the legs abducted and internally rotated can give some idea about the ability of the hip to reduce, with either increased acetabular coverage or a femoral osteotomy.
- A CT scan can provide a closer look at anterior and lateral coverage.
NONOPERATIVE MANAGEMENT

- Infants are typically treated with full-time braces, such as the Pavlik harness.
- Young children can be treated with a closed reduction and cast immobilization.
- The initial treatment for primary acetabular dysplasia without hip instability or residual acetabular dysplasia following treatment for instability is observation.
  - As long as the acetabular index continues to improve and the hip remains concentrically reduced, observation can be continued.
  - If hip subluxation develops or the acetabular index fails to improve over a 12-month period, operative treatment is indicated.
- Neuromuscular patients with a migration index less than 25% can be observed as long as their abduction remains greater than 45 degrees. Patients with migration indexes over 50% generally will benefit from surgical treatment of their dysplasia, which can include a femoral or pelvic osteotomy.

SURGICAL MANAGEMENT

- The Pemberton and Dega osteotomies are used to treat acetabular dysplasia with anterior and lateral deficiencies.
- They are used when more than 10 degrees of acetabular index correction is needed.
- They are also used to augment the reduction during open reduction in a patient with severe acetabular dysplasia.
- Mubarak’s variation of the Dega osteotomy incorporates a lateral ilium cut that goes all the way to the sciatic notch.
  - It includes a bicortical cut into the sciatic notch with a rongeur.
  - The inner wall of the ilium is cut only anteriorly between the anterosuperior and anteroinferior iliac spines (ASIS and AIIS) and posteriorly at the sciatic notch.

Preoperative Planning

- Hip and knee contractures should be carefully evaluated preoperatively so they can be addressed during the surgical procedure.
- With neuromuscular patients, the femoral head may be deformed. An open capsulotomy to look at the articular cartilage may prove to be beneficial.
- If there is significant articular cartilage damage, particularly laterally from the hip capsule, a resection arthroplasty may be indicated as opposed to a reduction.

The primary area of acetabular deficiency needs to be determined to plan the osteotomy.
- The triradiate cartilage should be open because the osteotomy hinges on this cartilage. Generally this osteotomy can be performed up to 10 years of age.
- Hip mobility must be good, especially abduction and internal rotation.
- A concentric reduction of the femoral head in the acetabulum before the osteotomy is an absolute prerequisite. This can be assessed preoperatively with an abduction internal rotation hip radiograph or can be assessed intraoperatively after a capsulotomy or varus proximal femoral osteotomy.

Positioning

- Patients are positioned supine on a radiolucent table with a bump under the lumbar sacral spine to provide about 30 degrees of elevation of the ipsilateral hip (FIG 3).
- A fluoroscopic evaluation should be done at this time to ensure adequate radiographic visualization.
- The entire limb is prepared from the lower rib cage to midline.

Approach

- A standard anterolateral approach using the interval between the tensor fascia lata and sartorius is used.

Either skin incision is deepened to expose the iliac crest and the interval between the sartorius and tensor fascia lata.
- The deep fascia is incised next on top of the tensor fascia lata muscle to avoid injury to the lateral femoral cutaneous nerve (TECH FIG 1B).
- The tensor–sartorius interval is deepened until the rectus femoris is encountered. The interval is then developed proximally up to the ASIS. The direct head of the rectus attached to the AIIS is identified. It can be released and reattached at the end of the osteotomy or left attached.
TECH FIG 1 • A. Skin incisions. There are two alternatives for the skin incision. The more extensile Smith-Petersen concave incision (red line) can be used for a concurrent femoral osteotomy, but it often leaves an unsightly scar. The more limited “bikini” incision (black line) provides plenty of exposure, leaves an appealing scar, and can be combined with a lateral incision for concurrent femoral osteotomies. B. Superficial exposure. The iliac apophysis has been exposed by elevating the overlying abdominal musculature. The tensor-sartorius interval has been opened. The interval is opened over the tensor musculature to protect the lateral femoral cutaneous nerve. The nerve is on top of the pickup.

PEMBERTON OSTEOTOMY

Deep Exposure

- The exposure is important in this osteotomy. Before any cuts are made the surgeon should be able to clearly see the inner and outer portions of the iliac wing to the sciatic notch posteriorly and the entire hip capsule anteriorly.
- The outer table of the ilium can be exposed either by splitting the iliac apophysis or by dissecting just below the apophysis, in which case the apophysis is then taken off as an entire piece to minimize injury to this growth area.
- The outer and inner tables are exposed in a subperiosteal fashion to the sciatic notch.
- Chandler retractors are placed into the sciatic notch from medial and lateral to protect the neurovascular bundle (TECH FIG 2).
- The reflected head of the rectus is then released and followed posteriorly. It acts as a guide to the border of the hip capsule.

Creating the Osteotomy

- The first cut is made on the outer table starting 1 to 1.5 cm above the AIIS and extending posteriorly and parallel to the joint capsule.
- About 0.5 to 1 cm from the sciatic notch, the osteotome should be turned and directed distally down the ischium to the level of the ischial limb of the triradiate cartilage (TECH FIG 3A).
- The last portion of this cut is made in a blind fashion with fluoroscopic guidance, and care must be taken to avoid cutting into the sciatic notch, the hip joint, or the triradiate cartilage.
- The osteotome should remain midway between the capsular attachment and the sciatic notch, splitting the posterior column in half to the level of the triradiate cartilage.
- The inner cut is started at the same point as the outer cut on the anterior surface, and the cut is generally at the same level as the outer cut running parallel to it (TECH FIG 3B).

Osteotomy Variation

- If more lateral coverage is needed, the inner cut is moved more distal and shortened to make a more oblique osteotomy.
- This changes the fulcrum of rotation from straight posterior to more posteromedial, giving more lateral coverage as the fragment is levered downward (TECH FIG 4).

Separating the Bone

- A special curved osteotome (TECH FIG 5A) is inserted into the osteotomy to connect the two cuts. This osteotome is advanced by hand.
- Once the osteotome is at the level of the triradiate cartilage (TECH FIG 5B), the acetabular roof is gently levered down (TECH FIG 5C).
TECH FIG 4 • Variations in the Pemberton osteotomy. The inner and outer iliac wing cuts determine the amount of coverage based on their direction. A,B. If more anterior coverage is required, then the inner cut is more transverse. C,D. If more lateral coverage is required, then the osteotomy is inclined laterally and both cuts begin a little farther away from the capsule.

TECH FIG 5 • A. Pemberton osteotome. The special curved Pemberton osteotome is necessary to connect the inner and outer wall cuts and make the sharp posterior curve. B. Connecting the cuts. A special curved osteotome is necessary to make the sharp curve of the osteotomy posteriorly. The osteotome is advanced by hand, connecting the inner and outer wall cuts made previously. The osteotome is advanced to the level of the triradiate cartilage. The dotted line represents the anterosuperior iliac spine autograft fragment that can be used to hold the osteotomy open. C. Levering down the osteotomy. The osteotomy is levered downward with the osteotome. A lamina spreader can also be used with caution. In this patient, a femoral shortening osteotomy and open reduction have been performed and sutures are in place allowing for a capsulorrhaphy once Pemberton osteotomy has been completed.
TECH FIG 6 • A. Anterosuperior iliac spine (ASIS) autograft bone wedge. An osteotome is used to harvest the ASIS autograft bone wedge. The height of the wedge is determined by the amount the osteotomy will be levered downward. B. Graft placement. An autograft bone wedge from the ASIS or an allograft wedge can be used. The graft is inserted in an anterior-to-posterior direction and should be stable after it is impacted. Internal fixation is seldom necessary. C. AP postoperative pelvic radiograph of a left Pemberton osteotomy in a spica cast. An open reduction, capsulorrhaphy, and femoral shortening osteotomy have also been performed.

Graft Placement and Closure
- Once the roof is in the desired position (usually an opening of 1 to 2 cm anteriorly), bone wedges are placed in the opening to hold the osteotomy open. Allograft or a wedge of the ASIS can be used. 5
- An autograft wedge of the ASIS can be harvested with a straight cut of the ilium (TECH FIG 6A).
- The graft is usually placed from anterior to posterior. A gouge may be used to make a trough in the iliac wing and the acetabular fragment for the graft to rest in (TECH FIG 6B).
- Internal fixation is usually not necessary.
- The apophysis and muscles are then reattached with suture, and the skin is closed in routine fashion.
- A hip spica cast is then applied (TECH FIG 6C).

DEGA OSTEOTOMY

Exposure
- As for the Pemberton osteotomy, the outer table of the ilium can be exposed either by splitting the iliac apophysis or by dissecting just below the apophysis, in which case the apophysis is then taken off as an entire piece to minimize injury to this growth area.
- The outer table is exposed in a subperiosteal fashion to the sciatic notch. Although it is not necessary to expose the inner table for a Dega osteotomy, it does aid in orientation and adds little to the morbidity of the procedure (TECH FIG 7).
- A Chandler retractor is placed into the sciatic notch from the lateral side to protect the neurovascular bundle.
- The reflected head of the rectus is then released and followed posteriorly. It acts as a guide to the border of the hip capsule.

TECH FIG 7 • Deep exposure. The iliac apophysis has been slit and the inner and outer walls of the ilium have been exposed by subperiosteal elevation. Sponges have been placed posteriorly along the inner and outer ilium to aid in retraction.
Creating the Osteotomy

- A curvilinear osteotomy is performed on the outer wall starting just above the AIIS to a point 1 to 1.5 cm in front of the sciatic notch.
- Guidewires can be inserted at the most cephalad portion of the osteotomy, directed toward the inner wall just above the triradiate cartilage. They are placed under radiographic guidance on the obturator oblique view. They serve as a guide for the chisel when the osteotomy is made.
- Like exposing the inner table, guidewires are not necessary but aid in orientation and add little to the morbidity of the operative procedure (TECH FIG 8A).

Next, an osteotome is used to cut the ilium medially and inferiorly in line with the guidewire down through the inner wall (TECH FIG 8B). If the inner table has been exposed, this can be confirmed with direct visualization. The posterior third of the inner wall should be left intact to act as a fulcrum for rotation.
- The less inner wall that is cut, the more lateral the coverage that will be obtained with rotation (TECH FIG 8C–E).
- The thinner the roof fragment, the deeper the coverage and less redirection you have.
- The cortex is then levered down with a wide osteotome to provide the desired coverage.
**Mubarak Variation**

- The Mubarak variation is a variation of the Dega osteotomy that incorporates a lateral ilium cut that goes all the way to the sciatic notch (TECH FIG 9).
- It includes a bicortical cut into the sciatic notch with a rongeur.

- The inner wall of the ilium is cut only anteriorly between the ASIS and AIIS and posteriorly at the sciatic notch.
- The outer ilium is exposed down to AIIS anteriorly and the sciatic notch posteriorly. The inner wall is exposed only enough to take the upper ilium and ASIS for bone graft.
- Two points are identified, one about 0.5 to 1 cm above the acetabulum and one within the sciatic notch. Bicortical cuts are made at each spot.
- A Kerrison rongeur can be used to make the posterior cut safely.
- A curvilinear cut is made in the outer cortex to connect the two points.
- The osteotome is directed down to the triradiate cartilage but does not enter the cartilage. It is used to lever the roof down 1 to 1.5 cm, and once the bone is levered down, bone graft wedges are used to hold it open.

**Graft Placement and Closure**

- Triangular bone wedges are used to hold the osteotomy open (TECH FIG 10A). Allograft wedges can be used. Autograft wedges from the iliac crest or from a concurrent femoral shortening osteotomy can also be used.
- The wedges are inserted in a lateral-to-medial direction. It is important to place the largest piece of graft where the most coverage is desired (TECH FIG 10B).
- Internal fixation is usually not necessary.
- The apophysis and muscles are then reattached with suture and the skin is closed in routine fashion.
- A hip spica cast is then applied (TECH FIG 10C,D).

**TECH FIG 9** • The Mubarak variation is shown in an anterior and lateral projection. The osteotomy extends anteriorly from the anteroinferior iliac spine posteriorly to the sciatic notch 0.5 to 1.0 cm above the hip capsule. The osteotomy is bicortical only in the area of the iliac spines and the sciatic notch. The sciatic notch cut can be made with a Kerrison rongeur. Osteotomes are then used to cut toward the triradiate cartilage between the hip joint and the medial wall. Once the cut has been extended to the triradiate cartilage, the acetabular fragment is levered downward. If the anterior and posterior cuts are not bicortical, then the fragment may not displace adequately.

**TECH FIG 10** • A. Triangular pieces of autograft or allograft bone can be used as wedges. The size of the wedge depends on the amount the osteotomy is mobilized and the remaining gap left. B. Autograft bone wedges from the anterosuperior iliac spine or allograft can be used. The grafts are inserted in a lateral-to-medial direction. The largest wedge is inserted in the area where the largest amount of coverage is desired. The grafts should be stable after they are impacted. Internal fixation is seldom necessary. C. Postoperative AP pelvic radiograph of a right Dega osteotomy in a spica cast (same child as shown in Fig 2B). Allograft bone has been used. D. An AP pelvic radiograph of the same child 12 months postoperatively. The line of Shenton is now intact, the allograft has incorporated nicely, and the femoral epiphysis remains round.
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Inadequate exposure</th>
<th>▪ If the sciatic notch cannot be seen on both the inner and outer walls of the ischium, then the osteotomy is more likely to enter the sciatic notch, potentially causing neurovascular injury.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Need lateral coverage</td>
<td>▪ The osteotomy should be more of an oblique osteotomy, and the length of the inner wall cut should be one-half to two-thirds the length of the outer cut. This allows the osteotomy to rotate around a more medial fulcrum, giving more lateral coverage.</td>
</tr>
<tr>
<td>Need anterior coverage</td>
<td>▪ The inner and outer wall cuts should be on the same level and the two cuts should be about the same length. For the Dega osteotomy, the inner cut might be slightly shorter (no less than 75% the length of the outer cut). This allows either osteotomy to rotate around a more posterior fulcrum, giving more anterior coverage.</td>
</tr>
</tbody>
</table>
| Graft loosening | ▪ A gouge can be used to make a trough for the graft.  
▪ Pemberton: The stability of the graft is tested with a Kocher clamp. If it is unstable, then the osteotomy is secured with a temporary Kirschner wire. The Kirschner wire must remain extrarticular.  
▪ Dega: The largest graft is placed in the area that needs the most coverage. The outer cortex of the graft should be buried below the outer cortex of the ilium. |
| Entry into the acetabulum | ▪ Without careful fluoroscopic guidance, the osteotome can be directed into the acetabular cartilage, causing significant damage. |
| Excessive anterior coverage | ▪ In a patient with prolonged subluxation or significant retroversion, the anterior coverage may subsequently leave the posterior acetabulum more unstable. |

POSTOPERATIVE CARE

▪ Patients are almost exclusively treated with a hip spica cast for 6 to 12 weeks. If this is a staged procedure, the patient should be left in half of the spica cast while the second procedure is being done.  
▪ Radiographs are obtained to make sure graft displacement has not occurred.  
▪ Once good radiographic healing has been demonstrated, progressive weight bearing over 4 weeks can be started.  
▪ Children are followed until maturity to detect avascular necrosis and ensure adequate acetabular coverage.  
▪ Physical therapy is typically not needed to regain mobility after immobilization.

OUTCOMES

▪ The Pemberton osteotomy provides excellent long-term acetabular correction in children, particularly those under age 4, 3, 8, 9, 13, 14.  
▪ The osteotomy has also been effective in patients with neuromuscular dysplasia.  
▪ The Dega osteotomy has been successfully used in the treatment of developmental dysplasia of the hip and neuromuscular dysplasia.  
▪ Several studies have found excellent results in younger children (under age 6), with results in older children less reliable.  

COMPLICATIONS

▪ Stiffness  
▪ Subluxation or dislocation  
▪ Closure of triradiate cartilage  
▪ Chondrolysis  
▪ Avascular necrosis of the femoral head

REFERENCES

DEFINITION
- The labral support (shelf) procedure has been used in patients with Legg-Calvé-Perthes disease (or Perthes disease) in Waldenström’s stages of necrosis or fragmentation in which the femoral head shows deformity or is at risk for deformity.\(^6\) (FIG. 1).
- The concept of the labral support (shelf) procedure in patients with Perthes disease includes the following steps:\(^6\):
  - Reducing the necrotic femoral head into the acetabulum
  - Eliminating hinge subluxation and improving femoral head coverage
  - Supporting the labrum and preventing deformity of the acetabulum (femoral–acetabular impingement)
  - Preparing for the (labral support) shelf to reabsorb after reossification of the femoral head
  - Stimulating overgrowth of the acetabulum and remodeling of the femoral head

ANATOMY
- The posterior branch lateral femoral cutaneous nerve
  - The lateral femoral cutaneous nerve arises from divisions of the second and third lumbar nerves.
  - It courses the lateral border of the psoas muscle, crosses the iliacus muscle obliquely, passes under the inguinal ligament, and divides into an anterior and posterior branch.
  - The posterior branch traverses beneath the sartorius muscle and exits the fascia lata about 1 to 2 cm below the anterior superior iliac spine.
  - The nerve supplies sensation to the skin anterolaterally from the level of the greater trochanter to the middle thigh.
  - The medial aspect of the bikini skin incision used in the labral support (shelf) procedure is very near the posterior branch of the lateral femoral cutaneous, which requires protection.
  - The labrum is located at the lateral rim of the acetabulum and has acetabular cartilage medially and fibrocartilage and fibrous tissue laterally.
  - The labrum growth plate contributes depth to the acetabulum and must not be damaged while performing the labral support (shelf).
  - In the adult, the average width of the acetabular labrum is 5.3 mm (standard deviation 2.6 mm).
  - The labrum is wider superiorly and anteriorly than posteriorly.
  - The surface area of the acetabulum without the labrum is 28.8 cm\(^2\) and with the labrum is 36.8 cm\(^2\).

PATHOGENESIS
- Perthes disease is a condition of the immature hip caused by necrosis of the epiphysis and the growth plate of the proximal capital area of the femur.
  - The necrotic tissue is gradually resorbed and replaced by new bone.
  - During the process, the epiphysis may become deformed and the growth of the proximal femur retarded.
  - Typically, the age at onset of symptoms is between 4 and 8 years, but it has been seen in children from 2 years to maturity.
  - There is a male predominance of 4:1, and the condition occurs bilaterally in up to 17% of cases.
  - Factors with the greatest prognostic significance in Perthes disease are:
    - Age at onset of the disease
    - Degree of necrosis of the capital epiphysis
    - Premature capital physeal growth plate closure
    - Persistent stiffness of the hip, with deformity of the femoral head (impingement)
  - At maturity, the hip may be normal or may have one of four patterns of deformity: coxa magna, coxa brevis, coxa irregularis (impingement), and osteochondritis dissecans.
  - In adulthood, patients with irregular (incongruent) hips develop impingement with progressive degenerative joint disease.
  - About 50% of all patients with Perthes disease have severe degenerative arthritis by the sixth and seventh decades of life.\(^{14–16,22}\)
NATURAL HISTORY

- Waldenström described four sequential stages of Perthes disease in childhood (later modified to the following): necrosis, fragmentation (resorption), reossification, and remodeling.\(^{24,25}\)
- The stage of necrosis begins with an infarction of the capital femoral epiphysis and lasts about 6 months.
- After the infarction, the child is usually asymptomatic, but a subchondral fracture subsequently develops in the necrotic bone and the hip becomes irritable (FIG 2).
- A mild effusion develops and the femoral heal begins to lateralize in the acetabulum.
- The hip becomes painful and adduction–flexion–external rotation contractures develop.
- The first radiographic sign of removal of necrotic bone begins the fragmentation stage (resorption).
- Gradually revascularization of the epiphysis begins, usually at the anterolateral area of the epiphysis.
- Over the ensuing months, the necrotic bone is removed, and the epiphysis may begin to deform, subluxate, and impinge on the margin of the acetabulum (hinged subluxation).
- During the fragmentation stage, the height of the lateral pillar of the femoral epiphysis correlates with outcome and predicts the chance of developing arthritis in adulthood (Table 1).
- The first radiographic signs of new bone formation indicate the reossification stage.
- About 12 to 14 months after the initial infarction, new bone begins forming in the epiphysis, usually at the anterolateral margin.
- Once the anterolateral column of the epiphysis has reossified, further epiphyseal deformity does not typically occur.\(^{23}\)
- Reossification continues until the entire epiphysis is healed, which may take up to about 4 years.
- The remodeling stage extends from the end of reossification until skeletal maturity.
- The femoral epiphysis may improve in sphericity with continued growth.
- Premature closure of the physis may cause limb shortening or deformity of the femoral neck.
- Common deformities of the hip following Perthes disease include coxa magna, coxa brevis (premature physeal closure), coxa irregularis (asphericity and incongruence of the hip with acetabular–femoral impingement), and osteochondral loose bodies.\(^{8,26}\)
- Stulberg et al\(^{22}\) classified hips into five groups that predict development of arthritis in adulthood (Table 2).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Perthes disease may present in children as an acute or chronic ache, which is commonly felt in the area of the hip, thigh, or knee. There is often an associated limp and hip stiffness.
- The ache is mild and usually presents immediately after getting up in the morning and after extended exercise, but it does not prevent walking.
- An antalgic limp is observed in the first few weeks of the disease, and then the gait may become a stiff pattern with flexion and adduction–flexion–external rotation contractures.
- The flexion–adduction hip contracture results in an apparent limb shortening, with dipping of the pelvis and a short stride length during ambulation.
- Muscle atrophy is often observed at the buttock, thigh, and knee.
- Additional clinical signs include a positive Thomas test (hip flexion contracture) and a positive log-roll test (loss of internal rotation of the hip).
- Growth in height is decreased during the early stages but returns to normal after healing.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- The diagnosis is typically confirmed by anteroposterior and frog-leg lateral radiographs.

</table>
Early in the disease (Waldenström stage of necrosis), radiographs show:
- Increased inferomedial joint space
- Lateral displacement of the femoral head
- Subchondral fracture
- Increased epiphyseal density
- A small proximal epiphysis of the femur

During the Waldenström stage of resorption (fragmentation), there is a gradual removal of the sclerotic necrotic bone and the femoral epiphysis may deform.
- As healing progresses with reossification, the epiphysis returns to a normal density and the femoral neck widens.
- The proximal femoral physis may close prematurely.\(^1\)

If the radiograph is not diagnostic, a bone scan or magnetic resonance imaging usually confirms the bone necrosis.
- The bone scan shows a cold area in the femoral epiphysis in the early stage of necrosis.
- With early revascularization (fragmentation stage of Waldenström), the scan will show the vascular ingrowth before radiographs.
- Magnetic resonance imaging clearly demonstrates the necrotic epiphysis in the early stage of the disease; however, marrow edema should not be confused with the area of necrosis.
- In the early stage, synovitis is observed, collapse and deformity of the cartilage of the epiphysis is usually clearly visible, and the degree of hinged subluxation (impingement) can be determined (FIG 3).\(^17\)
- In the fragmentation and reossification phases, vascular ingrowth is clearly visible.
- Computed tomography shows bone well and is most helpful to evaluate hip incongruity during the late stages of remodeling and during young adulthood.
- Skeletal hand bone age is decreased during the first year of the disease.

**DIFFERENTIAL DIAGNOSIS**
- Toxic synovitis (irritable hip syndrome)
- Infection, such as Lyme disease or tuberculosis
- Avascular necrosis of known etiology such as sickle cell disease, hemoglobinopathies, Gaucher disease, trauma, and steroid bone necrosis
- Arthritis, such as rheumatic fever
- Multiple epiphyseal dysplasia
- Tumors, such as chondroblastoma, leukemia, and lymphoma
- Slipped femoral epiphysis (preslip stage)

**NONOPERATIVE MANAGEMENT**
- Children less than 6 years of age without severe collapse of the femoral epiphysis have a good prognosis and do not require operative treatment.\(^2\)
- Their pain can be treated with nonnarcotic analgesic medications and crutch walking.
- Hip stiffness can be managed with physical therapy that emphasizes hip abduction, internal rotation, and extension.
- Children with necrosis involving less than 50% of the femoral epiphysis often have a good prognosis and operative treatment is often not necessary.
- Children over 11 years of age may be an exception in that a femoral epiphyseal deformity may develop (segmental collapse) even with less than 50% involvement.\(^10,20,26\)

**SURGICAL MANAGEMENT**
- **Indications**
  - Necrosis of over 50% of the proximal capital femoral epiphysis
  - Age 6 to 11 years: Younger children often heal well without operations and adolescents poorly remodel the femoral deformity.
  - Waldenström stages of necrosis or fragmentation. Ideally the operation should be performed before substantial deformity occurs to the capital femoral epiphysis.
  - Mild subluxation of the hip with hinged impingement (acetabular–femoral impingement)
- **Possible indications**
  - Children over 11 years of age with mild femoral epiphyseal collapse: These older children do not have adequate remaining growth to remodel the femoral epiphysis.
  - Children younger than 6 years of age with marked collapse of the femoral epiphysis: Typically children below 6 years of age heal well without treatment, but in severe cases, treatment may be indicated.
  - Patients with collapse of the epiphysis and hinged impingement: This operation may allow remodeling, but the outcome is less predictable.
- **Contraindications**
  - Subluxation that cannot be reduced into the acetabulum
  - Children less than 6 years of age (these patients heal well without treatment)
  - Necrosis less than 50% of the proximal capital femoral epiphysis (these cases typically heal well without treatment)
  - Children who are too old to achieve acetabular overgrowth: Children over 11 years of age may get less benefit.

**Positioning**
- The patient is placed in the supine position with the involved hip elevated by a longitudinal roll under the shoulder and back.
- The roll should not extend down to the hip area.
- The entire leg and hip is prepared and draped sterile to the anterior midline, to the posterior midline, and to the inferior rib line superiorly.

**FIG 3** Magnetic resonance image of the hip of a patient with Perthes disease showing lateral subluxation, synovitis, and acetabular–femoral impingement (hinged subluxation).
Approach
- The approach for the labral support procedure is between the tensor fasciae lata muscle and the sartorius and rectus femoris muscles.
- The dissection continues at the level of the anterior inferior iliac spine, beneath the origin of the gluteus minimus muscle (inferior gluteal line of ilium).
- The triangular interval is developed: the iliac wing medially, the hip capsule inferiorly, and the gluteus minimus laterally.
- With this approach, the origins of the abductor muscles are not elevated from the iliac wing, which we believe preserves the strength of hip abduction.
- The reflected tendon of the rectus muscle is retracted laterally and then used to secure the bone graft of the labral support shelf.

ARTHROGRAPHY
- Arthrography is performed to verify reduction of the subluxation and acetabular–femoral impingement.
- With the arthrographic dye in the hip joint, the degree of femoral epiphyseal deformity and subluxation is observed with the image intensifier.
- The leg is then abducted and the area of hinge abduction (acetabular–femoral impingement) is observed.
  - In many cases, the deformed femoral head will press against the lateral margin of the labrum and block the reduction of the femoral head into the acetabulum (TECH FIG 1A–C).
  - The arthrographic dye will pool in the medial–inferior joint, and with additional attempted abduction of the leg, the lateral margin of the labrum will deform upward.
  - In these cases, an adductor muscle tenotomy is then performed through a medial adductor incision.
  - Afterward, the leg is again abducted to determine the correction of the hinged abduction (ie, reduction of the weight-bearing surface of the femoral epiphysis within the acetabulum).
- The hip is considered to be reduced if the deformed part of the femoral head (weight-bearing area) is under the lateral margin of the acetabulum (contained within the acetabulum), the medial dye pool is reduced, and the lateral margin of the labrum is not deformed.
- If the hip reduces (TECH FIG 1D), proceed to operatively produce a bony shelf as described in the following section.
- If the reduction is incomplete, a capsulotomy of the inferior aspect of the hip capsule can be performed through the same incision as used for the adductor muscle tenotomy. Then the hip can again be tested to determine reduction.
- If reduction is achieved, proceed to operatively produce a bony shelf as described in the following section.
- If hip reduction cannot be obtained, I recommend the procedure be terminated and postoperatively the leg be placed in skin traction or a bilateral broomstick cast until a gradual hip reduction can be obtained.
- This is achieved by the patient’s legs being progressively abducted in the ensuing postoperative days until complete reduction is accomplished.
- The patient then returns to the operating room for continuation of the labral support shelf procedure.

TECH FIG 1 • A–C. Arthrograms of the hip of a patient with Perthes disease in which the leg is progressively abducted. The abnormal femoral head deforms the labrum with progressive abduction of the leg. D. AP radiograph of the hip of a patient with Perthes disease in which the femoral epiphysis is contained within the acetabulum as the leg is placed in abduction.
INCISION AND SUPERFICIAL DISSECTION

- The incision starts at a point 1 cm inferior to the anterior superior iliac crest and extends laterally along the skin lines of Langer for about 3 cm (TECH FIG 2).
- The dissection continues with a Cobb periosteal elevator between the tensor fasciae lata muscle and the sartorius and rectus femoris muscles.
  - The superior origins of the abductor muscles are not elevated from the outer wall of the iliac crest. I believe that maintaining the abductor muscles attached to the outer wall of the iliac wing improves postoperative hip abduction power.
  - With the periosteal elevator, a subperiosteal plane along the outer iliac wing about 3 cm wide is then developed beneath the gluteus medius and minimus muscles just above the hip. The image intensifier is useful to direct the periosteal elevator at a level of about 1 cm above the lateral margin of the acetabulum.

DEEP DISSECTION

- An arthroscope is helpful for visualization during the remainder of the procedure.
- The subperiosteal plane is developed further along the outer iliac wing over the hip capsule from the anterior inferior iliac spine toward the sciatic notch.
  - Caution is taken not to injure the labral growth cartilage of the acetabular margin.
  - The tendon of the reflected head of the rectus femoris, which is adherent to the hip capsule, is retracted laterally and preserved to be used later to support the bony shelf.
- The capsule is exposed with a periosteal elevator: anteriorly to the level of the anterior iliac spine, posteriorly to the sciatic notch, and laterally about 2 cm.
  - While exposing the capsule, do not injure the lateral growth plate of the acetabulum. (The capsule may be thickened, but it is never thinned.)

TROUGH CREATION AND GRAFT COLLECTION

- The level for the buttress shelf along the ilium is identified as about 3 mm above the labral growth plate of the acetabular rim. This corresponds to the superomedial margin of the hip capsule insertion into the ilium, a position that is verified with fluoroscopy by a metal marker (TECH FIG 3A).
- A trough is then developed at this level, as described by Staheli,19 by making a series of 1-cm-deep holes at the edge of the acetabulum using a 5/32-inch drill (TECH FIG 3B).
  - The holes should be directed upwardly about 20 degrees and extended posteriorly and anteriorly sufficiently to provide the needed coverage.
  - Care must be taken not to damage the cartilaginous margin of the acetabular growth plate.
  - An osteotome, narrow rongeur, or power burr (or a combination) is used to connect the holes to make a trough that is about 1 cm deep and angled cephalad about 15 degrees. The floor of the trough is the subchondral bone of the acetabulum and should be level with the capsule (TECH FIG 3C).
- Autogenous bone graft is obtained from the previously exposed outer wall of the iliac wing, which is just superior to the trough and beneath the gluteus medius muscle.
  - The graft is typically about $1 \times 1 \times 1.5$ cm and is cut into three longitudinal strips.
Chapter 72 LABRAL SUPPORT (SHELF) PROCEDURE FOR PERTHES DISEASE

CREATION OF THE SHELF

- Several absorbable sutures (usually three) are placed through the outer fibers of the hip capsule to be used later to secure the pieces of bone graft to the capsule.
- The leg is then placed in about 45 degrees of abduction and the deformed femoral head is again reduced into the acetabulum (contained), and this position is verified by the image intensifier. Caution: The femoral head must be contained within the acetabulum with no hinged subluxation, no deformity of the lateral labrum, and no impingement.
- The leg is held in abduction of 45 degrees, flexion of 15 degrees, and neutral rotation through the remainder of the procedure (and as the spica cast is applied).
- Autogenous bone graft is placed over the capsule, with the strips of bone inserted medially in the trough and laterally under the reflected head of the rectus femoris tendon, and the sutures are tied around the strips of graft to hold them snugly to the capsule (TECH FIG 4A).
- The reflected head of the rectus femoris tendon is placed over the lateral aspect of the graft to add additional support.
- About 30 to 60 mL of donor allograft bone may be added above the labral support (shelf) to create a buttress for additional support (TECH FIG 4B).
- The graft will appear extensive when visualized by the image intensifier.
  - The purpose of the shelf is to support the labrum and prevent the hip from anterolateral subluxation during reossification of the lateral column of the femoral epiphysis.
  - Remember: The shelf is expected to resorb in about 3 years because it is not expected to be weight bearing but only to act as a buttress with support of the acetabular labrum.
- The leg is held in abduction (as described earlier) with the femoral head in the reduced position as the incision is closed in layers.

The patient is placed in a one-and-one-half hip spica cast with the involved leg in abduction of 45 degrees, flexion of 15 degrees, and neutral rotation.

TECH FIG 3 • (continued) B. To begin creation of the trough, a line of upwardly inclined, 1-cm-deep holes is made where the rectus femoris tendon (now reflected) attaches to the acetabular margin. C. The holes are connected using a burr, osteotome, or narrow rongeur to create a slightly angled 1-cm-deep trough. An osteotome is then used to collect strips of cancellous and corticocancellous bone for the outer wall of the iliac wing.

TECH FIG 4 • A. Two layers of autogenous bone graft strips are placed over the capsule, one with the strips inserted lengthwise and the other with the pieces laid side by side widthwise. The strips of bone are inserted medially in the trough and laterally under the reflected head of the rectus femoris tendon. Strong, nonabsorbable sutures are used to anchor the graft into the capsule, and additional morselized bone graft is placed on top of the created shelf. B. AP arthrogram of the hip of a patient with Perthes disease in whom the femoral epiphysis and labrum is supported by a labral support (shelf) procedure.

POSTOPERATIVE CARE

- The cast, subsequent abduction contracture, and an abduction hip pillow at night offer initial containment. Later the labral support (shelf) acts as a buttress for the labrum to prevent resubluxation and hinging of the hip until the lateral column of femoral epiphysis reossifies.
- The cast is maintained for 6 weeks and the child is allowed to walk in the cast as soon as postoperative pain resolves.
- When the cast is removed, the patient is allowed to walk with “toe touch” crutch weight bearing for an additional 4 weeks and then allowed full ambulation without support.
- An abduction contracture of the hip is expected to persist additionally for about 6 weeks after cast removal.
- During the month after cast removal, an abduction hip pillow is used at night.
- Exercises of the hip are encouraged to maintain flexion, extension, and abduction; adduction is not encouraged for at least 6 to 8 weeks after the cast is removed.
- Abduction exercises of the hip to maintain at least 45 degrees abduction are continued until reossification of the lateral column of the femoral head.

OUTCOMES

- Domzalski et al reporting the results of 49 consecutive patients treated by the labral support (shelf) procedure for Perthes disease.
  - The procedure has a combined effect to prevent subluxation, to stimulate additional growth of the lateral rim of the acetabulum in a vertical dimension, and to provide temporary osseous containment until the shelf resorbs with time in a manner that is beneficial for preventing impingement of the femoral neck and greater trochanter on the shelf (FIG 4).
- Willett et al27 reported the results of 20 children treated by a lateral shelf acetabuloplasty and recommended its use in children over 8 years of age with Perthes disease of Catterall groups II, III, and IV.
- Van der Heyden and van Tongerloo28 reported on 25 patients with Perthes disease who were treated by a shelf procedure and had good or excellent results.
- Other authors have also reported encouraging results with similar labral support (shelf) procedures, but to my knowledge there has been no controlled, prospective, and randomized study comparing this procedure to other methods of treatment.

FIG 4 • AP radiographs of the hip of a patient with Perthes disease in whom the deformed femoral head was treated by a labral support (shelf) procedure. There is remodeling of the femoral epiphysis, widening of the acetabulum, and resolution of the shelf.
**COMPLICATIONS**

- Infection
- Injury of the labral growth cartilage, which prevents growth stimulation of the acetabulum
- Displacement of the labral support (shelf) bone graft
- Improper placement of the labral support (shelf)
- Neurovascular injury
- Cast problems

**REFERENCES**

Triple innominate osteotomy (TIO) is a surgical procedure that includes osteotomy of the ilium, ischium, and pubis, allowing rotation of the acetabulum around the femoral head (FIG 1). This greater freedom of rotation allows it to be used in cases (more severe dysplasia, older children) when the Salter innominate osteotomy would not provide enough rotation to cover the femoral head.

Because the procedure does not damage the triradiate cartilage, it can be used in skeletally immature patients without the risk of disrupting acetabular growth. Acetabulum size is maintained and redirected around the femoral head; the volume of the acetabulum remains constant but the weight-bearing surface is increased with improved femoral head coverage.

The TIO, often used for severe dysplasia, has the advantage of maintaining hyaline cartilage contact between the femoral head and acetabulum. This is in contrast to other procedures sometimes used to correct severe hip dysplasia or instability (shelf procedure, Chiari osteotomy) that must rely on repair tissue (fibrocartilage) to maintain a joint surface.

TIO is most commonly used for correction of acetabular dysplasia. Dysplasia may be a primary disorder or may result from incomplete treatment of developmental dysplasia of the hip (DDH); it is also seen as a result of neuromuscular conditions such as cerebral palsy, myelomeningocele, Down syndrome, and Charcot-Marie-Tooth syndrome.

TIO is also used to improve coverage and containment of a malformed femoral head, and for a combination of acetabular and femoral head deformities. Patients with Legg-Calvé-Perthes disease (Perthes disease), avascular necrosis (AVN), epiphyseal dysplasia, or an irregular femoral head resulting from a previous septic hip may also have poor femoral head coverage or dysplasia and benefit from TIO.

The acetabulum is formed by the ilium, ischium, and pubis, which in the immature pelvis are joined by the triradiate growth cartilage (FIG 2A,B). This complex, trilanged growth center allows the acetabulum to grow properly, providing a deep, stable hip joint. Injury to the triradiate cartilage by either fracture or an inappropriate acetabular osteotomy can alter the normal growth process, leading to hip dysplasia and subluxation.

The femoral head should be covered by the roof of the acetabulum.

The center–edge angle of Wiberg (angle between a line from the center of the femoral head to the lateral edge of the acetabular roof, and a vertical line drawn through the center of the femoral head) should be more than 25 degrees (FIG 2C).

Lateral subluxation of the femoral head can be measured as the percentage of the femoral head not covered by the acetabulum.

The acetabulum should be concave with a transverse sourcil (“eyebrow” in French) that turns down around the femoral head. Patients with hip dysplasia frequently have a very flat acetabulum with an upturned sourcil. This results in shear forces on the joint, leading to early degenerative joint disease.

The normal hip joint has a spherical femoral head that is congruent with a well-formed acetabulum.

Sphericity of the femoral head can be measured with Mose templates (concentric circles).

Deformity in Perthes disease or AVN can be measured as a percentage of the femoral head (lateral pillar) that has collapsed when compared to the contralateral side.9,10

Conditions that change femoral head sphericity lead to abnormal hip development and increased wear patterns within the joint (FIG 2D).

Hip Dysplasia

The high concordance between twins and studies noting that babies with parents or siblings with dysplasia have a much higher DDH incidence than the general population confirm a genetic component.

Mechanical factors also contribute to the risk for dysplasia. First babies and babies that are large have a higher risk, thought to be secondary to inadequate space in the uterus during development. Hip dysplasia is also commonly associated with torticollis and metatarsus adductus, with each of the three abnormalities thought to be a “packaging” problem.

There also appears to be a hormonal component, as girls and babies with increased laxity are at higher risk of hip dysplasia.
Legg-Calvé-Perthes Disease

- The cause of Perthes disease remains obscure, and it still can be thought of as idiopathic AVN of the hip in childhood.
- A few studies have shown a possible association between passive smoking and Perthes disease.\(^7\),\(^16\)
- Others have postulated that a deficiency in protein C leads to a hypercoagulable state, with thrombosis triggered by prothrombotic insults such as passive smoking.\(^17\)
- Because most Perthes patients have a delayed bone age, some have suggested that Perthes may represent a form of epiphyseal dysplasia. Delayed skeletal maturation is a routine finding in a typical Perthes case. The delay in maturation of the femoral head preossific nucleus may not adequately protect the vessels that ascend the femoral neck to the epiphysis, predisposing to AVN.

### NATURAL HISTORY

**Hip Dysplasia**

- Untreated hip dysplasia is the leading cause of premature hip arthritis that results in early total hip replacement. Abnormal sheer stresses on the hip lead to early osteoarthritis (OA), and the more severe the dysplasia, the more likely the development of arthritis.

**Legg-Calvé-Perthes Disease**

- The natural history for younger patients (under age 8 years at onset) and patients with milder disease (Herring A classification) is more benign, with minimal long-term disability.
- Children who are older at onset and who have more severe disease (Herring B or C classification) are more likely to develop femoral head deformity, which predisposes to early OA.

---

**FIG 2** Lateral (A) and medial (B) view 3D CT scans of an immature acetabulum with femur subtracted show that the triradiate cartilage is a growth center of the acetabulum that contributes to the ilium, ischium, and pubis. **C.** The center–edge (CE) angle of Wiberg is the angle created by a vertical line through the center of the femoral head and a line from the lateral edge of the acetabular roof to the center of the head. The normal hip on the left has a CE angle of 35 degrees; the dysplastic hip on the right has a CE angle of 15 degrees. **D.** Loss of sphericity of the left femoral head after reossification of Perthes disease has led to a noncongruent joint (left hip).
PATIENT HISTORY AND PHYSICAL FINDINGS

Hip Dysplasia
- Acetabular dysplasia is often asymptomatic in childhood and adolescence.
- Patients may have decreased abduction on examination, or pain with internal rotation of the hip. When they are present, symptoms are likely due to increased shear stresses, to labral damage, and later to OA.
- The pain is usually groin pain rather than lateral or trochanteric pain.

Legg-Calvé-Perthes Disease
- The disease may present as hip or knee pain.
- Early pain may be episodic.
- Patients with severe disease may have subluxation and more severe pain.
- A Trendelenburg gait is often noticed.
- Decreased abduction can be mild or severe.

A marked loss of abduction with the hip in the fully extended position (pelvis rotates rather than hip abducting) suggests hinge abduction and is a poor prognostic sign.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Anteroposterior (AP) plus frog-leg lateral plain radiographs provide two orthogonal views of the femoral head. However, to get two views of the acetabulum, a false profile radiograph should be taken in addition to the AP view. Both hips should always be imaged to allow comparison (FIG 3A–C).
- A dynamic arthrogram is the best way to determine the function and motion of the joint, since it allows visualization of the labrum and impingement of the femoral neck on the labrum or acetabulum. We advise a surgeon-performed arthrogram to evaluate the hip deformity and to assess for hinge abduction as well as the desired limb position after surgical correction (FIG 3D,E).
- Three-dimensional CT scans with reconstructions provide a better understanding of pathologic bony anatomy (FIG 3F).
- MRI with arthrogram helps to evaluate the labrum and joint space (FIG 3G).

FIG 3 • A, B. AP and frog-leg lateral radiographs of the pelvis show two views of the proximal femur but not of the acetabulum. C. To get another view of the acetabulum, a false profile view is obtained. Arthrogram (D) shows impingement in the abduction view (E). F. 3D CT scan clearly shows some dysplasia plus subluxation of the left hip. G. An MRI is the best study for evaluating labral tears (superolateral labral tear shown).
Differential Diagnosis
- Dysplasia secondary to DDH
- Dysplasia secondary to neuromuscular disease (eg, cerebral palsy, myelomeningocele, Charcot-Marie-Tooth disease)
- Dysplasia, subluxation secondary to syndromes (Down syndrome)
- AVN secondary to Perthes disease
- AVN secondary to steroid use, chemotherapy, metabolic disruption, infection, sickle cell disease
- Epiphyseal dysplasia with poor femoral head coverage

NONOPERATIVE MANAGEMENT

Hip Dysplasia
- From infancy to childhood (up to 18 months of age), if the hip is located within a dysplastic acetabulum, a Pavlik harness or abduction orthosis can be worn to treat the dysplasia.
- From age 18 months to 5 years, abduction bracing has not been found to predictably improve dysplasia, although nighttime brace use is occasionally recommended. Most advise monitoring during this period with hope that the acetabular growth centers will mature and correct the dysplasia.
- Older children with hip dysplasia are typically asymptomatic until the hip begins to have degenerative changes or a labral tear. Anti-inflammatory medications and activity modification can be used to decrease pain, but these do not correct the underlying problem and by masking symptoms may delay surgical correction. Therefore, medications should not be used for more than a short time. Instead, surgical correction should be performed to cover the femoral head and restore normal biomechanical forces.

Legg-Calvé-Perthes Disease
- Children younger than 8 years and patients with hips classified as Herring A can be treated conservatively with predictable results.
- Conservative treatment includes:
  - Activity modification and observation
  - Abduction exercises
  - Abduction bracing
  - Percutaneous adductor longus lengthening followed by Petrie casting or bracing to maintain abduction (FIG 4)

- Older children and those with Herring B and C hips require prolonged Petrie casting (rarely practiced) or surgical containment.

SURGICAL MANAGEMENT

General Principles

Hip Dysplasia
- Children under age 5 years can be treated nonoperatively unless the hip is dislocated and requires open reduction, or the dysplasia is very severe.
- Patients age 5 to 10 can be treated with an acetabular redirecting osteotomy that bends through the triradiate cartilage (Pemberton osteotomy, Chap. PE-71) or rotates through the pubic symphysis (Salter innominate osteotomy, Chap. PE-70).
- From the age of about 10 years until triradiate cartilage closure, a TIO is preferred for correction of dysplasia.
- Once the triradiate cartilage closes, TIO can still be performed, but a periacetabular osteotomy may be preferred because the posterior column remains intact, allowing earlier weight bearing.

Legg-Calvé-Perthes Disease
- Perthes disease can be treated nonoperatively in young children.
- Children older than 8 years or with more severe disease can be treated with a variety of surgical procedures aimed at containing the capital femoral epiphysis during the phase of reossification when the biologically plastic femoral head is at risk for subluxation, hinge abduction, and the development of permanent femoral head deformity.
- The simplest surgical treatment is adductor lengthening followed by Petrie casting or bracing. This can be used alone for very mild cases, or in preparation for containment surgery. Adductor lengthening and Petrie casting improves mobility of the hip and returns the hip to a more congruous, contained position, beginning the remodeling process that surgical containment will continue.
- Formal containment procedures include varus proximal femoral osteotomy (see Chap. PE-27) designed to direct the capital femoral epiphysis into the acetabulum.
- A Salter innominate osteotomy can also be performed, but Rab has clarified that the degree of acetabular rotation achieved with the Salter procedure is often not enough to cover the femoral head in more severe Perthes disease. A combined femoral and Salter procedure may be a better choice.
- TIO, which rotates the entire acetabulum around the femoral head, allows containment in more severe cases while avoiding the problems of femoral osteotomy (limp, limb shortening). This procedure has the benefit of maintaining hyaline cartilage surface-to-surface contact (as compared to the shelf or Chiari procedure).
- A shelf (labral support) osteotomy or Chiari procedure may be a better choice for a severely deformed femoral head that cannot be congruently centered in the acetabulum. With these procedures, contact between the hyaline (head) and hyaline cartilage (acetabulum) is partially sacrificed.

Preoperative Planning

Hip Dysplasia
- Radiographs and a 3D CT scan (if available) help in better understanding the nature and location of the acetabular...
deficiency. Typical dysplasia patients have an anterolateral deficiency. Children with neuromuscular disorders such as cerebral palsy, due to muscle imbalance around the hip joint and flexion contracture, often have a posterior deficiency.\textsuperscript{1,12,13}

- Once the amount and direction of dysplasia have been determined, acetabular rotation can be planned.
- Overrotation of the acetabulum should be avoided, as this can cause anterolateral impingement, which may hasten degenerative changes.
- Also, external rotation of the acetabulum should be avoided to prevent the creation of acetabular retroversion (which in itself can predispose to hip arthritis).

**Legg-Calvé-Perthes Disease**

- A preoperative dynamic arthrogram is the best study for understanding how to best contain the femoral head. We perform an arthrogram and percutaneous adductor lengthening followed by Petrie casting (for 6 weeks) before definitive containment surgery.

**Positioning**

- The patient is positioned supine on a radiolucent table. A Foley catheter can be considered to minimize any risk for bladder injury with the pubic ramus cut. This is advised for a surgeon’s initial cases but is often not needed once experience has been gained.
- A sandbag bolster is placed under the trunk to tip the patient toward the opposite side, giving better exposure of the hip laterally. The bolster should not be placed directly behind the pelvis because it often distorts the image intensifier views.
- The leg is draped free and the abdomen is prepared past the midline medially, to just below the nipple level superiorly, and around the buttock posteriorly—the ischial tuberosity must be kept in the surgical field (FIG 5).
- The C-arm and screen of the image intensifier are positioned to allow a clear view for the surgeon.

**Approach**

- TIO can be performed through two or three incisions. Using three incisions allows more precise exposure for each osteotomy cut, especially in larger patients.
  - The first incision is below the iliac crest as for a Salter osteotomy.
  - The second incision is distal to the groin crease, slightly below the superior pubic ramus, lateral to the adductor longus tendon origin and medial to the neurovascular bundle. The pubic osteotomy is performed through this incision with the ischial osteotomy also possible with posterior extension of the incision.
  - The third incision (if the surgeon chooses a three-incision approach) is longitudinal, distal to the gluteal crease, and just medial to the ischial spine with the hip flexed to 90 degrees.

**ILIAC OSTEOTOMY**

- An 8- to 10-cm Salter-type incision is made 1 cm below the iliac crest (TECH FIG 1A,B).
- The cartilaginous iliac crest apophysis is split, starting at the anterior superior iliac spine and continuing posteriorly for 6 to 8 cm.
- With care, this cartilage splitting can be carried anteriorly down to the anteroinferior iliac spine (TECH FIG 1C).
- Both sides of the iliac wing are exposed subperiosteally down to the sciatic notch using a Cobb periosteal elevator.
- Specially designed Rang retractors (Jantek Engineering, Paso Robles, CA) can be placed in the
PUBIC OSTEOTOMY

Earlier descriptions of TIO technique advised that the superior pubic ramus (TECH FIG 2A) be cut from the anterolateral Salter incision.
- We initially used this but then changed to a separate medial incision, which makes exposure very easy and avoids risk to the neurovascular bundle (due to overretraction with the anterolateral approach; TECH FIG 2B).
- For the three-incision technique, a 2- to 3-cm transverse incision (parallel to the inguinal ligament) is made just lateral to the adductor longus and 1 cm distal to the groin crease.
- For the two-incision technique, this incision would subsequently be extended medially and distally to allow exposure of the ischium.
- The pectineus muscle is identified just lateral to the adductor longus origin and is partially elevated off the superior pubic ramus. The saphenous vein, which often crosses the field, should be maintained and retracted laterally.
- The ramus is identified and Hohmann retractors are placed above and below the pubis extraperiosteally (TECH FIG 2C).

The extraperiosteal approach allows easier periosteal sectioning since the periosteum is strong in this area and may prevent movement of the pubic segment of the acetabuloplasty.
- Care must be taken to avoid the obturator nerve, which courses just below the superior ramus.
- Those new to the operation might be advised to begin with a subperiosteal approach to the pubic ramus.
- Fluoroscopy is used to confirm Hohmann retractor placement before making the osteotomy (TECH FIG 2D). The closer the surgeon is to the acetabulum, the easier it will be to rotate the acetabulum.
- Once position is confirmed, a narrow rongeur or osteotome can be used to make a slightly oblique osteotomy of the pubis. The cut can be angled slightly to allow subsequent superomedial acetabular displacement.
- If a rongeur is used (the safest method), the bits of excised bone should be maintained and returned to the osteotomy site to avoid the risk for pseudarthrosis.

PSOAS INTRAMUSCULAR LENGTHENING

At the distal end of the Salter incision, the structures are retracted on the medial side of the pelvic brim. The ilioischial muscles are identified and rotated to expose the psoas tendon, which lies posterior and medially in relation to the muscle mass of the ilioischial mass.
- Because the femoral nerve lies just anterior to the psoas muscle, care should be taken to identify the psoas tendon. A right-angled hemostat is placed around the tendon and the tendon is sectioned, leaving the muscle belly intact. This allows an intramuscular lengthening.
- The Salter incision can now be packed with a damp sponge and the wound edges pulled together with a towel clip while the other osteotomies are completed.

SCIATIC OSTEOTOMY

A sciatic notch to improve exposure (TECH FIG 1D), and a Gigli flexible wire saw is passed through the notch (TECH FIG 1E).
- The iliac osteotomy is then performed by bringing the Gigli saw anteriorly through the ilium, exiting at a point just above the anteroinferior iliac spine. In older, larger patients, we make this cut slightly more proximal than in a Salter osteotomy, which allows room to place a temporary Schanz screw to guide the acetabular segment.
**ISCHIAL OSTEOTOMY**

- The three-dimensional nature of the ascending ischium, buried deeply in muscle, is not easy to comprehend. When first performing this procedure, the surgeon should have a skeletal model of the pelvis in the operating room and the circulating nurse should hold it for him or her to inspect as needed. The proximity of the ischial spine to the sciatic nerve must be appreciated.
- One error that we have seen is palpation of a deep bony prominence, thought to be the ischial spine, which was in fact the greater trochanter. The hip should be kept rotated internally to avoid this error.

**Two-Incision Technique**

- Through the adductor incision, blunt dissection is carried out subcutaneously down to the ischial spine.
- The electrocautery is used to take down the posterior portion of the adductor magnus muscle origin just anterior to the proximal origin of the hamstrings.
- The ischial tuberosity is identified and then an initial sharp Hohmann retractor is placed inside the obturator foramen.
- A Cobb elevator is then used to clear the ischium up to its origin just below the acetabulum.
- Blunt Hohmann retractors are then placed extraperiosteally around the ischium, with one retractor in the obturator foramen and the other lateral to the ischium.
- Using a mallet to tap a blunt Hohmann into these spaces makes it easier (helps to safely elevate the thick periosteum and tendon origins; TECH FIG 3A,B).
- This is a very deep exposure, and the neophyte will be surprised at the depth of the ascending ischium.
- Finally, a third Hohmann retractor (sharp) is driven into the ischial bone just below the acetabulum to allow easier superior retraction (TECH FIG 3C).
- Thus, there are a total of three Hohmann retractors—one medial, one lateral, and a sharp-tipped tapped into the bone proximally.
- Fluoroscopy is used to check position. The ischial cut should be just below but not in the acetabulum (about 1 cm below the lower end of the “teardrop”).
TECH FIG 3 • A. The third cut is the ischial cut. B. Two Hohmann retractors are placed around the ischium. Tapping the retractors with a mallet helps to get them positioned. C. A third sharp Hohmann is driven into the ischium in the proximal end of the wound (just below the acetabulum) to help with retraction. The osteotome can then be introduced. D. When the osteotome enters the posterior cortex, it is rotated medially to displace the ischium.

- Once position is confirmed, a rongeur can be used to start the osteotomy, creating a groove for the osteotome to prevent the osteotome from slipping.
- A long straight osteotome is then inserted and used to complete the osteotomy.
  - To encourage proper displacement of the osteotomy, the large wooden handle of the osteotome is used to radically rotate the acetabular segment medially before the osteotome is withdrawn. This begins the desired medial displacement of the ischium (TECH FIG 3D).
  - Using a very long (about 20 inch) wooden-handled osteotome makes this essential rotational maneuver easier.

Three-Incision Technique

- The hip is flexed to 90 degrees and a third incision is made longitudinally in the buttock just distal to the gluteal crease and medial to the ischial tuberosity (TECH FIG 4).
- Otherwise the technique is identical to that noted above.

TECH FIG 4 • If a third incision is to be used, it is made just proximal to the gluteal crease, medial to the ischial spine.
ROTATION OF THE ACETABULUM

- The packing sponges are now removed from the Salter incision. A temporary Schanz screw is placed in the acetabular segment just above the hip joint to use as a handle to guide acetabular positioning (TECH FIG 5A).
- A long ballpoint pusher is placed in the superior pubic ramus just lateral to the pubic cut and impacted into the bone (TECH FIG 5B,C). This is pushed upward and inward while the Schanz screw is levered downward and laterally to rotate the entire acetabulum around the femoral head.
- A Cobb elevator is placed in the Salter (iliac) cut and rotated to encourage lateral positioning of the acetabular fragment in the coronal plane. Care must be taken not to externally rotate the acetabular segment (this is easy to do in a triple osteotomy and will cause undesired acetabular retroversion).
- To avoid undesirable external rotation, Salter’s advice that “even after the osteotomy the anterior superior and anterior inferior iliac spines should remain aligned” should be adhered to as well when a triple osteotomy is performed.
- Through the Salter incision, a wedge of bone is removed from the iliac crest using an oscillating saw (TECH FIG 5D). The base of the wedge should be fashioned to fit tightly in the gap of the iliac osteotomy (TECH FIG 5E).
- This triangular graft is only about half as large as in a Salter osteotomy for the same-size patient since a good deal of the rotation should have occurred in the pubic and ischial cuts.
- The osteotomy is first fixed with temporary, sturdy smooth Kirschner wires (TECH FIG 5F).
- Acetabular position is checked with fluoroscopy to confirm the amount of coverage that has been obtained.

**TECH FIG 5** • A. A Schanz screw is placed just above the hip (arrow); it can be used as a lever to help rotate the acetabulum. B. A ballpoint pusher can be used to push the pubic portion upward and inward while the Schanz screw levers the superior acetabulum anterolaterally. C. Fluoroscopic image showing ballpoint pusher (white arrow) and Schanz screw (black arrow). D,E. Bone graft is taken from the iliac crest and fashioned to fit into the iliac osteotomy. F. The osteotomy is temporarily fixed using smooth Kirschner wires to confirm position with fluoroscopy before final screw fixation.
FIXATION OF THE OSTEOTOMIES

- 4.5-mm fully threaded screws can be inserted from the iliac crest across the bone graft and into the superior acetabular bone.
- Using fully threaded screws minimizes the tendency for loss of correction that can occur when a partially threaded screw is tightened too much, overcompressing the graft and pulling the acetabular edge upward. Instead, the screws should stabilize and maintain some distraction.
- We use two or three screws to adequately fix the acetabular fragment.
  - Threaded Kirschner wires can be used in smaller patients in whom the bone may not be thick (strong) enough to hold the 4.5-mm screw.
  - We prefer screws because later removal is easier.
- In older, larger patients, we often place a single screw from medial to lateral across the pubic osteotomy to prevent further rotation of the acetabular fragment or nonunion of the pubis (TECH FIG 6A).
- A second method for pubic ramus fixation includes a screw on either side of the pubic cut pulled together with a 20-gauge wire (TECH FIG 6B).
- Any remaining bone graft fragments can be packed into the pubic and ischial osteotomies to prevent nonunion.

WOUND CLOSURE

- All of the incisions are thoroughly irrigated.
- The iliac crest apophysis is reapproximated and closed with a running absorbable suture. Hemovac drains are placed in the Salter, pubic, and ischial incisions.
- The incisions are then closed in layers with absorbable suture.
- Sterile dressings are applied. In most cases, a single hip spica is applied.
- If both iliac and pubic fixation is secure in a cooperative patient, we sometimes use a removable bivalve plastic “spica-type” orthosis (made before surgery) or trust the patient with no immobilization (rare).

PEARLS AND PITFALLS

Intraoperative fluoroscopy
- The surgeon must remember that the patient has a bump to slightly elevate the operative side, and fluoroscopy needs to accommodate for this tilt: the pelvis is not parallel to the floor. Before rotating the acetabulum, it is helpful to position the machine to get a good AP view of the pelvis with symmetric teardrops; do not try to calculate the acetabular segment position from an oblique fluoroscopic image.

Acetabular positioning
- Proper rotation of the acetabulum is the most important part of this procedure. Overrotation anteriorly will produce anterior impingement, which is indicated by a crossover sign on the radiograph and an overly prominent ischial spine (FIG 6A) overrotation laterally can produce lateral impingement or hinge abduction.
- We have developed several standards to help us evaluate acetabular rotation on radiography or fluoroscopy (FIG 6B).
In smaller children, threaded pins can be used instead of screws. It is important to have at least three points of fixation in the ilium to prevent postoperative motion and rotation.

If the osteotomies are not well fixed, or weight bearing is started too early, the acetabulum may change position, leading to overcorrection (protrusio-like) or loss of correction.

We have experienced both pubic and ischial nonunions in older children. To prevent this we often add a pubic ramus screw and replace any excised bone back into the osteotomy sites.

The iliac crest will grow over the screw heads or tips of the threaded pins if they are flush with the crest. Leaving the implants slightly prominent or attaching a nonabsorbable suture to the screw head on one end and to the subcutaneous tissues on the other facilitates later implant removal.

We recommend a single-leg spica cast for 6 weeks followed by partial weight bearing with crutches for an additional 4 weeks. If adequate bone healing is noted on radiography, activity can then be advanced as tolerated.

Physical therapy may be useful for regaining abductor strength and motion.

The fixation screws can be removed 6 to 12 months postoperatively (if you elect to remove them). Whether the screw presence will hinder or compromise a later total hip replacement remains unclear. Clearly, femoral implants should be removed, but some consider acetabular screw removal less important. We lean toward removal of all implants from the hip in these patients, as they may require a later total hip replacement.

As TIO is most commonly used for late juveniles, adolescents, and young adults, very long-term follow-up studies are required to evaluate function over a lifetime, with 30 to 60 years of follow-up.

Unfortunately, these long-term studies have not yet been done. There are several studies that look at short- to medium-term results.

Guille et al8 reported more than 10 years of follow-up on 11 patients aged 11 to 16 with symptomatic hip dysplasia treated with TIO. Ten hips improved radiographically, eight improved functionally, and one required total hip arthroplasty.

Faciszewski et al3 followed 56 hips in 44 patients that underwent TIO for 2 to 12 years. Improvement in pain and function was considered good in 53 hips. Three hips were considered failures.

Peters et al20 evaluated 60 hips in 50 patients undergoing TIO. At an average 9-year follow-up, 12 (20%) hips had been converted to total hip arthroplasty and 4 (7%) hips had incapacitating pain. Radiographically, there was significant improvement in the center–edge angle of Wiberg and the acetab-
ular angle of Sharp. There also was a statistically significant relationship between failure of the osteotomy and severity of pre-existing hip arthrosis.

When evaluating any procedure, it is important to evaluate the quality of each individual procedure, which is difficult to do in the literature. We have found through our own experience that the quality of the surgical procedure and the anticipated outcomes improve dramatically with surgeon experience.

When done properly and for the correct indication, TIO can improve the radiographs and symptoms of patients with hip deformity, whether the deformity is acetabular, femoral, or a combination of both.

The procedure is not without risks, and occasional patients have a poor outcome.

- In patients with acetabular dysplasia, indications and outcomes are better understood.
- The application of TIO for patients with femoral deformity (Perthes, AVN, epiphyseal dysplasia) has a shorter track record, but the procedure appears to provide clear benefit in properly selected cases.

**COMPLICATIONS**

- Inadequate coverage or containment
- Creation of impingement either anteriorly or laterally
- Sciatic or peroneal division nerve injury
- Injury to the bladder, spermatic cord, obturator nerve, sciatic nerve
- Loss of fixation or acetabular rotation
- Infection
- Nonunion of pubis or ischium
- Hip stiffness
- Progression to OA
- Need for further surgery (deimpingement procedure, valgus rescue osteotomy of femur, Chiari osteotomy, shelf acetabuloplasty, hip fusion, total hip arthroplasty)

**REFERENCES**

DEFINITION
- The Chiari osteotomy is primarily a “salvage” osteotomy for acetabular dysplasia in the painful, unstable hip.
- It is generally reserved for hips where a congruous reduction is not possible because of arthrosis or femoral head asphericity that prevents use of one of the more standard rotational osteotomies.1,4,5
- It is a single pericapsular osteotomy through the iliac (innominate) bone of the pelvis with medialization of the acetabulum and hip joint to improve posterior and lateral coverage. The ilium forms a shelf over the dysplastic, subluxated hip (FIG 1).
- The goals are improved femoral head coverage, a stable articulation, and metaplastic transformation of the hip capsule to fibrocartilage to create a stable, pain-free hip.
- Contraindications include severe arthrosis, age greater than 45 (relative, where arthroplasty may be a better option), and significant proximal migration of the femoral head (may prevent adequate coverage by thinner proximal ilium).5

ANATOMY
- Developmental acetabular dysplasia most commonly involves deficiency of the anterior and anterolateral acetabulum.
- In cases of spastic hip dysplasia, the lateral and posterolateral acetabulum is most often deficient.
- The location of acetabular deficiency must be considered when planning the shape and orientation of the osteotomy and positioning of the iliac shelf over the hip joint.
- Femoral head deformity may include coxa breva, coxa magna, or coxa plana.
- In cases of trochanteric overgrowth, simultaneous advancement of the greater trochanter may provide improved abductor mechanics (although the risk of heterotopic ossification may be slightly increased).
- This osteotomy may not provide adequate coverage in cases of high dislocation and in the pelvis in patients with advanced neurologic conditions (eg, myelomeningocele, Chapter 74)

FIG 1 • Concept and steps of the Chiari osteotomy. A. The view required to properly perform the osteotomy. B. The proper placement of the osteotomy in the coronal plane is at the superior border of the acetabulum, just above the capsule and angled upward 10 to 15 degrees. C. The acetabular fragment is displaced medially, hinging on the symphysis pubis. D. The proposed osteotomy (dotted line) as seen from the lateral projection. E. The line of the osteotomy as seen from the inside view of the pelvis. It is above the triradiate cartilage.
where the ilium is very thin above the acetabulum). Therefore, careful consideration of the available periacetabular bone stock should be made before considering the Chiari osteotomy.

- The need for additional bone graft to supplement posterior, lateral, and (especially) anterior coverage is common.
- This procedure does not require concentric reduction of the femoral head into the acetabulum.
- It has the advantage of medializing the femoral head and decreasing the force across the hip joint by increasing the surface area of coverage.
- Lateralizing the ilium to form a shelf causes obligatory shortening of the gluteal muscle length and abductor moment arm that weakens the muscle and contributes to postoperative Trendelenburg limp. However, advancing the greater trochanter can restore the resting length of the gluteus medius. Delp et al found that decreasing the obliquity of the supra-acetabular osteotomy may decrease the effect on the abductor lever arm.

**PATHOGENESIS**

- The causes of advanced hip disease requiring salvage surgery are many and include late diagnosis of developmental dysplasia of the hip (DDH), spastic or neuromuscular hip dysplasia, failed prior hip procedures (reduction, periacetabular osteotomy), and acetabular trauma.
- Femoral head conditions that can lead to incomplete or incongruous femoral head coverage include primary malformation, secondary avascular necrosis, slipped capital femoral epiphysis, epiphyseal–metaphyseal dysplasia, and secondary malformation from longstanding subluxation or impingement.

**NATURAL HISTORY**

- Because this osteotomy is used as a salvage procedure for many hip diseases, it can be used to treat any of the several conditions that result in progressive, painful arthrosis and instability.
- The threshold of acetabular dysplasia required to induce arthrosis is incompletely understood. However, when assessing lateral uncovering, Murphy found that a lateral center–edge angle less than 16 degrees on an anteroposterior (AP) view of the pelvis correlated with a significantly increased risk of requiring arthroplasty by age 65.
- Spastic hip dysplasia can lead to progressive subluxation and painful dislocation in 30% to 50% of cases. It is more common in nonambulatory patients.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Key portions of the history include:
  - Personal or family history of or treatment for DDH
  - History of other hip disorders, including Legg-Calvé-Perthes disease
  - Trauma
  - Skeletal dysplasias
  - History of cerebral palsy
  - Birth order and weight
  - Description of pain and mechanical symptoms, including location, duration, activity limitation, giving way, clicking, catching, and popping
- The physical examination should include gait, limb length, assistive devices, and strength.
- Specific hip tests include the following:
  - Trendelenburg test: Demonstrates weakness in abductors
  - Anterior apprehension test with extension and external rotation of the hip: A positive result is a subjective noting of “apprehension” or instability by the patient.
  - Gluteus medius and maximus strength
  - Anterior impingement test (pain with passive hip flexion, adduction, and internal rotation): Test of anterior labral pathology, not just a tear
  - “Bicycle test” for abductor fatigability of the hip while lying in the contralateral decubitus position
  - Range of motion: It is important to test internal and external rotation at multiple degrees of flexion as femoral head and acetabular deformities vary. This can often aid in determining where the pathologic articulation is located.
  - Galeazzi sign: Demonstrates hip subluxation or dislocation
- The Chiari osteotomy can increase abduction. It does not always significantly improve range of motion in other planes, and therefore preoperative flexion to 90 degrees, full (or near full) extension, and at least 10 to 20 degrees of adduction are requirements.
- Gait is assessed preoperatively. It is important to discern whether any limp is antalgic, due to abductor weakness or instability. The Chiari osteotomy classically can improve antalgia and instability. However, the patient should understand that abductor weakness may not be improved.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiography should include weight-bearing anteroposterior (AP) views of bilateral hips, false profile of hips, and AP of hips in maximal abduction and internal rotation (FIG 2).
These studies allow assessment of lateral and anterior coverage of the femoral head as well as congruency of the hip joint. Also noted will be the presence of hinge abduction.

- Computed tomography (CT) scan with three-dimensional reconstruction may help in preoperatively assessing the amount and direction of acetabular deficiency.
- Magnetic resonance imaging (MRI) of involved hips with radial sequences centered at the femoral head can also help with preoperative assessment of articular and labral cartilage.

**DIFFERENTIAL DIAGNOSIS**

- DDH
- Spastic hip dysplasia
- Legg-Calvé-Perthes disease, avascular necrosis
- Multiple or spondyloepiphyseal dysplasia
- Posttraumatic hip or femoral dysplasia

**NONOPERATIVE MANAGEMENT**

- The patient being considered for Chiari osteotomy usually presents with pain and arthrosis.
- Activity and job modification and weight loss may be of benefit in delaying or mitigating the onset of arthritic symptoms.
- Physical therapy may be of some benefit in increasing range of motion and strength. To date, there are no data to suggest that a specific physical therapy regimen can stop the onset of arthritis in the dysplastic hip.

**SURGICAL MANAGEMENT**

- Hip adductor tenotomy, lengthening, or Botox can be used in an attempt to delay the onset of spastic hip dysplasia (if performed before age 4 to 6) and if hip abduction is less than 45 degrees with hips flexed and extended.
- This is especially important if a varus intertrochanteric osteotomy is being performed simultaneously.
- Painful, unstable, moderate to severe dysplasia with incongruent articulation with or without femoral head deformity often requires surgical correction.
- Additional options to Chiari include arthrodesis, shelf procedures, and arthroplasty.

**Preoperative Planning**

- A complete physical examination is performed and radiographs are obtained.
- In the case of marked proximal migration, preoperative traction for 2 to 3 weeks may improve the position of the femoral head relative to the acetabulum, thereby increasing proximal ilial fragment coverage after osteotomy.

**Positioning**

- The patient is placed supine on a radiolucent table with a rolled blanket bump under the operative hip.
- All other bony prominences are carefully padded.
- A Foley catheter is placed and prophylactic antibiotics are administered.
- The use of epidural anesthesia depends on patient and surgeon preferences.
- The extremity is prepared free proximally to the costophrenic margin, including the groin and buttock regions.

**Approach**

- The ilioinguinal approach begins along the iliac crest and continues medially for about 10 cm.
- The iliofemoral approach is less cosmetic but can aid in visualization in larger patients and can allow combined pelvic and femoral procedures to be done through one incision.

**EXPOSURE**

- The skin incision begins laterally 1 to 1.5 cm below the iliac crest, extending distally to 1.5 cm below the anterior superior iliac spine and then posteriorly over the lateral thigh or medially across the groin to 1.5 to 2 cm medial to the anterior superior iliac spine (ilioinguinal approach; TECH FIG 1A).
- The tensor fascia lata (TFL) compartment is entered just lateral to its intermuscular septum with the sartorius muscle, which is retracted medially.
- The TFL muscle belly is bluntly dissected off the intermuscular septum and dissection is carried proximally to the ilium. This allows visualization of the anterior ilium and easy continuation of subperiosteal exposure of the ilium (TECH FIG 1B).
- Although the lateral femoral cutaneous nerve is not routinely visualized or isolated, it may be encountered underneath the fascia in the interval between the sartorius and the TFL. Therefore, care should be taken when retracting the medial structures during this dissection, the procedure, and closure of the interval.
- The iliac apophysis is split (in younger patients) or subperiosteally dissected (in skeletally mature patients) to allow subperiosteal exposure of the inner and outer tables of the ilium. A moist sponge is packed along the inner table to provide retraction and hemostasis.
- The outer table of the ilium is subperiosteally cleared of abductor musculature. This is carried out until a firm endpoint is reached, usually indicating that the surgeon has reached the indirect head of the rectus femoris.
- Expose the anterior and superior aspects of the hip joint capsule. Identify the rectus femoris, release the indirect head at its bifurcation from the direct head, and follow...
TECH FIG 1 • (continued) C. The outer table of the ilium is exposed. A Lane bone lever placed subperiosteally into the greater sciatic notch allows excellent visualization of the acetabular rim (arrow) all the way to the ischial spine.

OSTEOTOMY

- Once the exposure is complete, a variety of methods may be used to create the osteotomy.
- The supra-acetabular osteotomy is a curvilinear cut from the anterior ilium, along the capsular edge of the acetabulum, and posterior to the greater sciatic notch. We use a modification advocated by Hall that simply makes a concerted effort to create a dome osteotomy by curving the osteotomy distally when aiming for the notch to maximize the posterior coverage.
- While Chiari originally described a semi-blind osteotomy, it is important to have excellent visualization of the superior hip capsule from the anterior ilium to the greater sciatic notch and along the posterior wall of the acetabulum to the ischial spine. Placement of the osteotomy must be at the capsular edge of the acetabulum (TECH FIG 1C).

TECH FIG 2 • A–C. Bone models demonstrate the planned supra-acetabular osteotomy using a combination of curved and dome-shaped osteotomes. D. Scoring the inner table of the ilium along the projected course of the osteotomy minimizes splintering. E. AP fluoroscopic view of the right hip during osteotomy. The osteotome enters at the edge of the acetabulum and is directed upward at an angle of about 10 to 15 degrees (see Fig 1A). This facilitates “sliding down” of the ilium over the hip joint capsule. When properly completed, the cut surface of the ilium will lie in direct
contact with the hip capsule and will be in continuity with the lateral bony edge of the acetabulum.

**Chiari Conventional Method**
- A Gigli saw is passed through the greater sciatic notch while protecting its contents and is used in a posterior-to-anterior direction.
- We find that as the starting point is crucial, it is helpful to notch the posterior column in the sciatic notch and the outer table of the ilium to create a track for the Gigli.

**Authors’ Preferred Method**
- We prefer a combination of curved and dome-shaped osteotomes used under fluoroscopic guidance to create the osteotomy.
- It is often helpful to score the inner table of the ilium along the projected course of the osteotomy to minimize splintering of the inner table (TECH FIG 2A–F).
- To maximize the amount of posterior coverage, an attempt is made to continue the osteotomy at the acetabular rim as far distal and posterior as possible.
- This is carried out only to a level just above the ischial spine (TECH FIG 2G).

**ACETABULAR DISPLACEMENT**
- The hip is abducted and pushed medially to displace the distal fragment (TECH FIG 3A,B).
- The amount of displacement required is somewhat dependent on the amount of coverage required. One hundred percent displacement is possible and often necessary.

In particular, when posterior coverage is required, the ilium is displaced posteriorly over the sciatic notch; take care to prevent compression or entrapment of the sciatic nerve (TECH FIG 3C).

**OSTEOTOMY FIXATION**
- The osteotomy is fixed in place with 3.5- or 4.5-mm cortical screws placed either along the iliac crest or along the outer table of the ilium under fluoroscopic guidance directed into the posterior column of the ischium (TECH FIG 4A,B).
- If additional coverage is required (especially anterior), a corticocancellous graft is excised from the inner table of the ilium using a saw or osteotome (TECH FIG 4C). This fragment is interposed between the hip capsule and the

(continued)
WOUND CLOSURE

- Drains can be used at the surgeon's discretion.
- The iliac apophysis is closed with heavy, absorbable, interrupted sutures.
- The remainder of the wound is closed in layers.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Indications</th>
<th>Proper patient selection. Severe arthrosis or proximal migration may be incompletely managed by Chiari osteotomy. Care should be taken when considering this procedure in young patients or in patients with neuromuscular disease as they may have insufficient thickness of ilium to provide adequate coverage.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Osteotomy</td>
<td>Curving the osteotomy distally and posteriorly toward the sciatic notch maximizes posterior coverage. The more dome-like the osteotomy, the more anterior coverage is afforded. The posterior osteotomy may follow the posterior acetabulum as far distally as the ischial spine. Then it must be carried posteriorly to the notch, exiting proximal to the sacrospinous ligament. Again, the contents of the sciatic notch must be carefully protected by subperiosteal placement of retractors.</td>
</tr>
<tr>
<td>Screw fixation</td>
<td>Screws are placed at the iliac crest for fixation. However, with increased displacement it may be necessary to start the screws along the outer table of the ilium. They are directed into the posterior column of the ischium under fluoroscopic guidance.</td>
</tr>
<tr>
<td>Additional coverage</td>
<td>A corticocancellous segment of the inner table of the ilium is used as bone graft for augmenting deficient (especially anterior) coverage.</td>
</tr>
<tr>
<td>Sciatic nerve</td>
<td>Careful subperiosteal dissection of the sciatic notch will help to protect the neurovascular contents. We recommend palpation of the posterior edge of the osteotomy after displacement to confirm there is no soft tissue (sciatic nerve) entrapment.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Patients are kept toe-touch weight bearing for 6 weeks.
- Range of motion is allowed from full extension to 70 degrees of flexion.
- Therapy is allowed for gentle passive range of motion within these limits for 6 weeks.
- Weight bearing is advanced with evidence of radiographic healing.
- If trochanteric advancement was performed, active abduction is limited for 6 weeks.
- Patients who have a neuromuscular condition with spasticity or underwent tendon lengthenings in the same surgery are placed in either bilateral long-leg casts held in abduction by a connector bar or knee immobilizers and abduction foam pillow.
- Neuromuscular patients will stay in the immobilization for 3 weeks. After 3 weeks patients come out of immobilization for gentle passive range of motion and bathing for an additional 3 weeks.

OUTCOMES

- In general, reported outcomes with follow-up from 11 to 34 years are good to excellent for pain relief.\textsuperscript{1,2,4,5,7,8}
- Outcomes are better for younger patients with mobile hips (at least 90 degrees of flexion) and adequate corrected coverage.

COMPLICATIONS

- Sciatic neuropraxia from sciatic nerve entrapment or injury during osteotomy or neuropraxia of the lateral femoral cutaneous nerve
- Incomplete correction and resubluxation
- Heterotopic ossification
- Infection
REFERENCES

DEFINITION

- Hip dysplasia is the most common etiology of coxarthrosis, often leading to arthroplasty long before joint replacement can be considered a lifetime solution.³
- Surgical realignment of the congruous dysplastic acetabulum can improve or eliminate symptoms for years, sometimes indefinitely, in a majority of appropriately selected patients, even in those with some degree of preoperative arthrosis.¹³⁴⁶⁸
- Age limits for this procedure are adolescence (closed triradiate cartilage) to an indefinite upper age limit (limited by preoperative arthrosis and other considerations that might make arthroplasty a better choice).

ANATOMY

- The acetabulum lies between the anterior and posterior columns of the pelvis.
- The most common area of acetabular deficiency in developmental dysplasia of the hip (DDH) is anterior and lateral.
- The Bernese periacetabular osteotomy (PAO) differs from the triple osteotomy primarily by maintaining the integrity of the posterior column of the pelvis.
- The Bernese PAO uses five steps to divide the acetabular fragment from the remainder of the pelvis, allowing multplanar realignment.
- Important bony landmarks include:
  - Iliopsoas tendon (which marks the most anterior extent of the acetabulum)
  - Infracotyloid groove (just distal to the acetabulum, where the obturator externus tendon lies; this is the site of the anterior ischial osteotomy)
  - Anterosuperior iliac spine (ASIS)
  - Apex of the greater sciatic notch
  - Ischial spine
- The posterior column is triangular and thickest just posterior to the acetabulum; it becomes much thinner closer to the sciatic notch. For this reason, the optimal plane for the posterior column is angled obliquely to the medial cortex and perpendicular to the lateral cortex of the ischium–posterior column.

PATHOGENESIS

- Genetic and developmental causes exist for “developmental dysplasia.”
- Neuromuscular: Charcot-Marie-Tooth disease and spastic diplegia
- Posttraumatic: injuries to the triradiate cartilage; aggressive excision of the limbus in the infant hip

NATURAL HISTORY

- There is a clear correlation between acetabular dysplasia and osteoarthrosis of the hip.
- The more severe the acetabular dysplasia and any subluxation, the earlier the onset of symptoms from arthrosis.
- Murphy et al⁵ found that every patient with a lateral center–edge angle less than 16 degrees developed osteoarthritis by age 65.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Key portions of the history include:
  - Personal or family history or treatment of DDH
  - History of other hip disorders, including Legg-Calvé-Perthes
  - Trauma
  - Skeletal dysplasias
  - History of cerebral palsy
  - Birth order and weight
  - Description of pain or mechanical symptoms, including location, duration, activity limitation, giving way, “clicking,” “catching,” and “popping”
- Physical examination should include gait, limb length, assistive devices, and strength.
- Specific hip tests include the following:
  - Trendelenburg test: Demonstrates weakness in abductors.
  - Anterior apprehension test: A positive result is a subjective noting of “apprehension” or instability by the patient.
  - Anterior impingement test (pain with passive hip flexion, adduction, and internal rotation): Test of anterior labral pathology, not just a tear.
  - Bicycle test for abductor fatigability.
  - Range of motion (ROM): Dysplastic hips may demonstrate a relative increase in flexion due to anterior acetabular uncoverage. Decreased ROM with pain may indicate arthrosis.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Radiography includes weight-bearing anteroposterior (AP) views of bilateral hips (FIG 1A), false profile of hips (FIG 1B), and AP views of the hips in maximal abduction and internal rotation (von Rosen view; FIG 1C). These studies allow assessment of lateral and anterior coverage of the femoral head as well as congruency of the hip joint. Additionally noted will be presence of hinge abduction, which is a relative contraindication to PAO.
- Radiographic parameters include the following:
  - Lateral center–edge angle of Wiberg measured from AP view of the hip (lower limits of normal about 25 degrees; see Fig 1A)
  - Anterior center–edge angle of Lequesne and de Seze (lower limits of normal 20 degrees measured on the false profile view; see Fig 1B)
  - Tönnis acetabular roof angle measured on the AP view of the hip (upper limits of normal 10 to 15 degrees; FIG 1D)
Crossover sign (anterior wall shadow crossing posterior wall shadow on AP view of the pelvis)
Assessment of the line of Shenton for breaks indicative of femoral head subluxation
Computed tomography (CT) scan of both hips with three-dimensional reconstruction as well as with axial slices through the femoral condyles may be of assistance in preoperatively assessing the amount and direction of correction required as well as the potential need for proximal femoral osteotomy.
Magnetic resonance imaging (MRI) of involved hips with radial sequences centered at the femoral head allows assessment of articular and labral cartilage.
Delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) is a recently developed technique that assesses the mechanical damage to the articular cartilage. It has been demonstrated to be a better preoperative predictor than plain radiographs in determining outcome after PAO.²

NONOPERATIVE MANAGEMENT
Activity and job modification may be of benefit in delaying or mitigating arthritic symptoms.
Physical therapy may be of some benefit in increasing ROM and strength. To date, there are no data to suggest that a specific therapy regimen can affect the onset of arthritis in the dysplastic hip.

SURGICAL MANAGEMENT
Indication: Symptomatic, congruous acetabular dysplasia (closed triradiate cartilage) with lateral and anterior center-edge angles 18 degrees or less
Contraindications: Tönnis osteoarthrosis grade 2 or more (subchondral cysts, significant joint space narrowing); severe limitation of motion secondary to arthrosis; active joint infection

Preoperative Planning
Radiographs and MRI are evaluated to assess the following:
Degree and character of dysplasia
Amount and direction of correction required to normalize the Tönnis acetabular roof angle (0 to 10 degrees), correct subluxation, and improve mechanical stability
Proximal femoral deformity may also require treatment at time of PAO.
Presence of acetabular articular or labral lesions (seen on MRI) should also be taken into consideration, as treatment either arthroscopically (before the osteotomy) or intraoperatively through limited arthroscopy may be required for best long-term results.
Isolated treatment of a labral lesion in the presence of acetabular dysplasia is contraindicated. Simultaneous acetabular realignment must be considered.
The torn acetabular labrum is usually associated with other structural abnormality within the hip (femoral acetabular impingement or DDH), which may also require correction for best results.⁹
Partial weight-bearing technique is taught preoperatively in preparation for postoperative mobilization.

Positioning
The patient is positioned supine on a radiolucent table.
The operative extremity is prepared and draped free up to the costal margin; the surgeon should be certain to prepare and drape posteriorly to at least the posterior third of the ilium and medially to the umbilicus.
Analgesia: We typically use an epidural for perioperative pain management; it is removed by postoperative day 3. However, this is not mandatory.

Approach
- The standard longitudinal anterior Smith-Petersen incision and approach to the hip provides the appropriate access (FIG 2A).
- As an alternative, an ilioinguinal (bikini) incision may be used followed by a similar deep approach (FIG 2B). This incision typically provides a better cosmetic result but can limit access for the anterior ischial osteotomy. Therefore, we recommend the standard anterior incision for larger and more muscular patients.

FIG 2 • A. Hip with traditional Smith-Petersen incision marked. B. Hip with bikini-type incision marked.

SUPERFICIAL DISSECTION
- The skin is incised into subcutaneous tissue.
- The fascia over the external oblique and gluteus medius is identified and incised posterior to the ASIS and the plane between the two muscles is developed to expose the periosteum over the iliac crest.
- The periosteum is sharply divided over the iliac crest and subperiosteal dissection carried out over the inner table of the ilium. This space is packed with sponges for hemostasis.
- Entry into the tensor fascia lata-sartorius interval is initially accomplished via the compartment of the proximal tensor fascia lata to avoid injury to the lateral femoral cutaneous nerve. The tensor fascia lata is bluntly elevated off the intermuscular septum and the compartment floor is identified proximally until the anterior ilium is palpated. Once hemostasis is attained, the ASIS is predrilled with a 2.5-mm drill and the anterior 1 x 1 x 1-cm portion is osteotomized to facilitate the medial dissection and later repair.
- Alternatively, the sartorius can be taken off with just a thin wafer of bone that will be sewn back in place at the end instead of with a screw.
- Subperiosteal dissection is continued to the anteroinferior iliac spine (AIIS).

DEEP DISSECTION
- Flexion and adduction of the hip facilitates the deep intrapelvic and superior ramus dissection.
- The reflected head of the rectus femoris is divided at its junction with the direct head (TECH FIG 1A,B).
- The direct head and underlying capsular iliaca are elevated as a unit and reflected distally and medially off the underlying joint capsule.
- The iliaca, sartorius, and abdominal contents are reflected medially.
- The psoas sheath is opened longitudinally, and the
psoas tendon is retracted medially to allow access to the superior pubic ramus medial to the iliopsectineal eminence.
- The interval between the medial joint capsule and the iliopsoas tendon is created and sequentially dilated using the tip of a long-handled Mayo scissor, then further by Lane bone levers, with the tips of each palpating the anterior ischium at the infracotyloid groove.
- Proper placement of the scissor and bone levers can be confirmed with the image intensifier (TECH FIG 1C,D).

OSTEOTOMIES

Anterior Ischial Osteotomy
- With the hip flexed 45 degrees and slightly adducted, a 30-degree forked, angled bone chisel (Synthes, USA; in 15- or 20-mm blade widths) is carefully inserted through the previously created interval between the medial capsule and psoas tendon to place its tip in contact with the superior portion of the infracotyloid groove of the anterior ischium, just superior to the obturator externus tendon (TECH FIG 2A–C).
- Staying proximal to the obturator externus tendon helps to protect the nearby medial femoral circumflex artery.

The medial and lateral aspects of the ischium should be gently palpated with the chisel. Proper chisel placement (about 1 cm below the inferior acetabular lip) is confirmed on AP and oblique projections with the image intensifier (TECH FIG 2D).
- The osteotome is impacted in a posterior direction to a depth of 15 to 20 mm in a posterior direction and through both medial and lateral cortices of the ischium (TECH FIG 2E).
- Care should be taken not to drive the osteotome too deeply through the lateral cortex, as the sciatic nerve is nearby.
Superior Pubic Ramus Osteotomy

- The hip is kept flexed and adducted to relax the anterior soft tissues.
- The psoas tendon and medial structures are gently retracted medially (TECH FIG 3A).
- After circumferential subperiosteal dissection of the ramus, either a spiked Hohmann retractor or a large-gauge Kirschner wire is impacted into the superior aspect of the ramus at least 1 cm medial to the iliopectineal eminence (TECH FIG 3B).
- Blunt Hohmann retractors, Rang retractors, or Lane bone levers are placed anteriorly and posteriorly as well as inferior to the ramus to protect the obturator nerve and artery.
- The osteotomy is perpendicular to the long axis of the ramus when viewed from above but oblique from distal-medial to proximal-lateral when viewed from the front and may be carried out either by passing a Gigli saw around the ramus and sawing upward away from the retractors or by impacting a straight osteotome just lateral to the spiked Hohmann or Kirschner wire. In the former method, the Gigli saw is passed with the aid of a Satinsky vascular clamp.
- The key to this osteotomy is to stay medial to the iliopectineal eminence and avoid entering the medial acetabulum (TECH FIG 3C).
- Arthrotomy and intracapsular inspection: At a point before all osteotomies are completed, an arthrotomy may be performed to identify and treat intra-articular lesions such as a torn labrum or impingement lesions of the femoral head and neck.
- This is closed loosely with simple, interrupted absorbable suture before proceeding with the remainder of the osteotomies.
The iliacus is retracted medially with a reverse Hohmann with its tip on the quadrilateral surface. Under direct vision the iliac osteotomy is performed with an oscillating saw and cooling irrigation in line with the Hohmann retractor until reaching a point about 1 cm above the iliopectineal line (well anterior to the notch). This end point of the iliac saw cut represents the posteroinferior corner of the PAO. This corner is also the starting point of the posterior column osteotomy, which will be midway between the sciatic notch and posterior acetabulum (TECH FIG 4).

At this point, a single Schanz screw on T-handled chuck is inserted into the acetabular fragment distal and parallel to the iliac saw cut, well above the dome of the acetabulum, into a hole predrilled with a 3.2-mm drill.

**Posterior Column Osteotomy**

- The leg is once again flexed and adducted to relax the medial soft tissues.
- A reverse blunt Hohmann retractor is placed medially with the tip on the ischial spine. Dissection into the sciatic notch is neither necessary nor recommended.
- The osteotomy is made through the medial cortex with a long, straight 1.5-cm osteotome. It extends from the posterior end of the iliac saw cut, passing over the iliopectineal line, through the medial quadrilateral plate, parallel to the anterior edge of the sciatic notch on iliac oblique fluoroscopy, and is directed toward the ischial spine (TECH FIG 5A).
- This osteotomy must extend at least 4 cm below the iliopectineal line to avoid entry into the acetabulum when completing the final (posteroinferior) infraacetabular osteotomy. This posterior cut is made first through the medial, then second through the lateral wall of the ischium.
- The ischium is wider here than at its anterior extent. If pictured from above, it resembles a triangle with the narrower apex at the anterior edge of the sciatic notch. Therefore, the surgeon should not

**Supra-acetabular Iliac Osteotomy**

- A 1.5- to 2-mm subperiosteal window is started beneath the anterior abductors just distal to the ASIS without disturbing the abductor origin.
- The leg is slightly abducted and extended to allow atraumatic subperiosteal dissection using a narrow elevator posteriorly toward, but not into, the apex of the greater sciatic notch.
- A narrow, long, spiked Hohmann retractor is placed in this window. Correct placement is confirmed with image intensifier; in the lateral projection the spike of the Hohmann should point toward the apex of the sciatic notch (TECH FIG 3C).
ACETABULAR DISPLACEMENT

- A 1-inch straight Lambotte chisel is placed into the supraacetabular iliac saw cut to both confirm completion of the lateral cortex osteotomy and protect the cancellous bone above the acetabulum during displacement.
- The tines of a Weber bone clamp are placed onto the superior ramus portion of the acetabular fragment in such a way as to place its handle anterior and in contact with the Schanz screw (TECH FIG 7A).
- A lamina spreader is placed into the iliac osteotomy between the posterosuperior intact ilium and the Lambotte chisel anteriorly.
- While gently opening the lamina spreader, the Schanz screw and Weber clamp are used to mobilize the acetabular fragment. It is important to ascertain whether the posterior and anterior osteotomies are complete; otherwise, the fragment will not freely rotate and the common outcome will be distal and lateral displacement as you hinge on the lateral, intact cortices. These cuts can be inspected with a narrow or broad 30-degree chisel (TECH FIG 7B).
- Once the fragment is completely free, it may be positioned to obtain the desired correction. As previously noted, the most common deficiency is anterior and lateral. Therefore, the most commonly used maneuvers are to lift the acetabular fragment slightly toward the ceiling, creating an initial displacement, followed by a three-step movement of lateral, distal, and internal rotation.
- When performed properly, the posterosuperior corner of the acetabular fragment should be impacted slightly into the superior intact iliac cut and the prominent superior tip of the acetabular fragment should be roughly in line with the superior intact iliac crest (TECH FIG 7C).
- The radiographic “teardrop” and its relation to the femoral head after fragment positioning should be ele-
ACETABULAR FIXATION

- Once the desired acetabular position is obtained, 3/32-inch smooth Kirschner wires (the approximate diameter of a 2.5-mm drill) are placed proximal to distal through the ilium and into the fragment in a divergent pattern.
- At this point we perform a final fragment position check in the AP and false profile views (TECH FIG 8A,B).
- Importantly, in the false profile view, we check the anterior femoral head coverage in full extension and at 100 degrees of flexion (TECH FIG 8C). In the former view, the sourcil should be roughly horizontal, the femoral head should be well covered, and the line of Shenton should be intact. The false profile view is to confirm that we have neither overcovered the femoral head nor created impingement from a femoral-sided deformity.

(continued)
If there is less than 90 degrees of flexion on palpation or radiograph, it may be necessary to either reposition the fragment or address femoral-sided deformity.

- The Kirschner wires are measured for depth and length and then replaced with either 3.5-mm or 4.5-mm cortical screws.
- The image intensifier is used to confirm extra-articular placement of all screws (TECH FIG 8D,E).
- An additional “home run” screw may be placed anterior to posterior from the AIIS posteriorly into the inferior ilium if required for stability (especially in patients who are ligamentously lax or have a neuromuscular condition or poor bone quality). We prefer not to use this screw unless necessary, as it is our practice to remove these screws once bony healing is confirmed for screw head irritation or in case MRI is to be performed at a later point. The anterior iliac prominence of the acetabular fragment is trimmed and used for bone graft.
- Gelfoam is placed along osteotomy sites to assist with hemostasis.

WOUND CLOSURE

- All sponges are removed and wounds are irrigated copiously.
- Suction drains are placed under the iliacus.
- The ASIS osteotomy (if performed) is reattached either by using a 3.5-mm, partially threaded cancellous screw and washer or by being sewn back with heavy, absorbable suture through thinner wafer.
- Careful attention is paid to proper, tight closure over the iliac crest. This is accomplished by predrilling holes in the iliac crest to facilitate passage of heavy, absorbable sutures to reattach the abductor, iliacus, and external oblique musculature.
- The remainder of the wound is closed in layers.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Patient selection</th>
<th>Appropriate patient selection is paramount.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Risk factors for failure include older age, poor congruency, decreased joint space (less than 2 mm), and advanced arthrosis.</td>
</tr>
<tr>
<td></td>
<td>Presence of a labral tear preoperatively may also be an indicator of degeneration, more than may be apparent on plain radiographs.</td>
</tr>
<tr>
<td>Pubic osteotomy</td>
<td>The hip should be flexed 40 to 50 degrees for making the pubis osteotomy, which takes tension off the iliopsoas and improves access to the brim of the pelvis.</td>
</tr>
<tr>
<td>Ischial osteotomy</td>
<td>If the medial joint is entered while attempting to gain access for the ischial cut, the surgeon can open the psoas sheath and try a second approach dissecting through the floor of the sheath. This technique can be helpful in re-establishing an extra-articular dissection to the ischium.</td>
</tr>
<tr>
<td></td>
<td>Straying too medial risks injury to the neurovascular bundle.</td>
</tr>
<tr>
<td>Iliac osteotomy</td>
<td>In general, given true supine positioning of the pelvis and patient, the iliac wing osteotomy will be roughly directed perpendicular to the floor. This sighting technique gives a second visual reference, which, in combination with intraoperative imaging, will aid in proper positioning of the osteotomy.</td>
</tr>
<tr>
<td>Incomplete osteotomies</td>
<td>Connecting the inferior ischial (infraacetabular) osteotomy and the posterior ischial cuts may require a medial-to-lateral osteotomy cut through their medial junction. This is most commonly necessary when the lateral portion of these osteotomies is incomplete and the finding is an inability to freely move the acetabular fragment at the initial completion of all planned osteotomies.</td>
</tr>
<tr>
<td>Schanz screw placement</td>
<td>The Schanz pin (screw) should be placed nearly in line with and 1 to 1.5 cm below the iliac wing osteotomy. In poorer-quality bone, it may be necessary to place the screw closer to the acetabular subchondral bone. Additionally, the acetabular fragment should be mobilized by using both the Schanz pin and the bone clamp holding the pubic portion of the free fragment.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE
- Sitting is permitted on postoperative day 2.
- Partial weight bearing is reviewed by a physical therapist once the epidural catheter is removed on postoperative day 2 or 3.
- Weight bearing is progressed from partial to full, typically by 6 to 8 weeks with radiographic healing and return of abductor strength.
- Range of motion is limited to 90 degrees of flexion, 10 degrees from full extension, and 10 degrees of adduction, abduction, and rotation for the first 6 weeks.
- Resistive exercises are avoided for 3 months.
- Patients older than 16 years are given either low-molecular-weight heparin or warfarin for 4 to 6 weeks.
- Nonsteroidal anti-inflammatories are avoided.

OUTCOMES
- Outcomes are generally good to excellent in the appropriately selected patient.
- Hips with minimal arthrosis (more than 2 mm of joint space and no significant subchondral changes) in younger (less than 35 years old) patients have demonstrated significant improvement in Harris hip and Merle D’Aubigne scores that can last at least 20 years.1,3,4,6–8
- Hips with moderate to advanced arthrosis in older patients can still show significant improvement in symptoms. However, their symptom relief may be shorter-lived, requiring conversion to either a surface replacement or total hip arthroplasty.

COMPLICATIONS
- Sciatic or lateral femoral cutaneous nerve palsy
- Postoperative wound hematoma requiring return to operating room
- Wound infection
- Nonunion of pubic ramus
- Heterotopic ossification
- Vascular injury
- Intra-articular osteotomy
- Malalignment of fragment leading to insufficient correction or overcorrection

REFERENCES
DEFINITION

- Surgical dislocation of the hip can be done safely to treat a number of conditions, including femoroacetabular impingement (FAI), labral tears, chondral injuries, reduction of femoral neck fractures, reduction of acute severe slipped capital femoral epiphysis (SCFE), or any condition that requires wide complete access to the hip joint.\(^9\)

- There is little morbidity associated with this procedure, and avascular necrosis of the femoral head is a rare complication.\(^2\)

- This technique allows functional assessment of motion intraoperatively.

ANATOMY

- The blood supply to the femoral head is mainly from the medial femoral circumflex artery (MFCA) (FIG 1A).\(^{10}\)

- The intact external rotator muscles, most notably the obturator externus muscle, protect the MFCA during the dislocation (FIG 1B).\(^4\)

PATHOGENESIS

- In FAI, anatomic deformity leads to abnormal contact between the proximal femur and the acetabular rim at the terminal extent of motion.

- In cam impingement, an abnormal bump on the femoral neck passes into the hip beneath the labrum and mechanically damages the labrum and cartilage of the acetabulum.

- Pincer impingement occurs with overcoverage of the acetabular rim impinging on the anterior femoral neck or head–neck junction with terminal flexion.

- Both cam and pincer impingement can, and frequently do, coexist.

- The early chondral and labral lesions that occur in physically active adolescents and young adults can progress and result in degenerative joint disease of the hip.

- Causes of FAI can be idiopathic, secondary to a SCFE, anterior overcoverage of the hip with a retroverted acetabulum, residual deformity from Perthes disease, or posttraumatic changes.

NATURAL HISTORY

- A pistol-grip deformity of the femoral head has been associated with early arthrosis of the hip.\(^6\)

- End-stage osteoarthritis of the hip, once thought to be mainly idiopathic, is now believed to be a result of mild deformities similar to those caused by childhood diseases of the hip such as developmental hip dysplasia, SCFE, and Legg-Calvé-Perthes.\(^1\)

PATIENT HISTORY AND PHYSICAL FINDINGS

- FAI usually presents in active adolescents or young adults with slow-onset groin pain, which may be exacerbated by athletic activities.

---

**FIG 1** • A. Vascular anatomy of the femoral head. Note the proximity of the terminal branches of the medial femoral circumflex artery (MFCA) to the insertion of the piriformis tendon. **B.** Intraoperative photograph showing the path of the MFCA over and behind the intact short external rotators, including the quadratus femoris (Q) and the obturator externus (OE).
Many patients have difficulty sitting for long periods and adjust their seating posture to decrease lumbar lordosis to allow less flexion at the hips. Frequently they complain of difficulty getting into or out of a car.

There can be a family history of hip pain, early arthrosis, or hip arthroplasty.

Patients may walk with an antalgic gait, favoring the side of impingement. A foot-progression angle externally rotated may indicate a chronic SCFE or femoral retroversion.

The impingement test, if positive, shows reproducible groin pain with internal rotation, which is relieved with external rotation.

The physical examination should include both flexion and internal rotation range-of-motion tests.

Patients with impingement will have less than 90 degrees of true hip flexion.

Patients with impingement will have less internal rotation in flexion than extension, and may have a compensatory external rotation of the hip as it is flexed.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Plain radiographs should include an anteroposterior (AP) view of the pelvis and a true lateral view of the hip held in 15 to 20 degrees of internal rotation (FIG 2A,B).

Computed tomography scans with two- and three-dimensional reconstructions are helpful for preoperative planning and detecting subtle femoral head-neck junction prominence (FIG 2C,D).

Magnetic resonance imaging can further delineate the labral and cartilage pathology (FIG 2E). If the study is performed with gadolinium and high-resolution sagittal oblique or radial sequences, labral pathology can be detected.

**FIG 2** • AP pelvis (A) and true lateral (B) radiographs, which show the lack of femoral head–neck offset anteriorly (arrow in B) that is causing cam impingement. Three-dimensional reconstructions of the same pelvis from an AP (C) and a slightly left-rotated (D) perspective. The large “bumps” (arrows) obscuring the anterior femoral head–neck junction account for the lack of offset appreciated in B. E, T1-weighted sagittal MRI showing a large anterior osteophyte (arrow).
DIFFERENTIAL DIAGNOSIS
- FAI
- Labral tear
- Hip dysplasia
- SCFE
- Acetabular retroversion

NONOPERATIVE MANAGEMENT
- Nonoperative management includes cessation of aggravating activities, and symptomatic treatment using nonsteroidal anti-inflammatories.
- Physical therapy to strengthen the hip musculature does not address the mechanical impingement of FAI.

SURGICAL MANAGEMENT
- Hip pathology may be addressed through hip arthroscopy. However, it may be difficult to dynamically assess hip mechanics before and after débridement.
- Femoral head-neck osteoplasty may be performed through an anterior approach to the hip without a surgical dislocation. However, the articular cartilage of the acetabulum and most of the femoral head cannot be evaluated with this limited approach.

Preoperative Planning
- All imaging studies are reviewed.
- The lack of femoral head–neck offset is best appreciated on the true lateral view of the hip (see Fig 2A,B), or on the axial cuts or 3D reconstruction of a CT scan.

A CT scan that includes cuts through the distal femoral condyles may be used to accurately measure the amount of femoral version.7
- After general anesthesia is administered, the patient’s hips are examined. The amount of true hip flexion and internal and external rotation with the hip extended and hip flexed are noted and compared to the preoperative assessment.

Positioning
- The patient is placed in the full lateral position, secured on a pegboard. A flat-top cushion (with a half-moon-shaped cutout for the down leg) placed beneath the operative side helps to stabilize the leg during the approach (FIG 3A–C).
- A hip drape with a sterile side bag is used, which will capture the leg during the dislocation maneuver (FIG 3D).

Approach
- The approach consists of an anterior dislocation through a Kocher-Langenbeck or a Gibson approach with a trochanteric flip osteotomy (FIG 4A,B).
- A Kocher-Langenbeck incision is followed by splitting the gluteus maximus muscle.
- The abductors and gluteus maximus muscles can be spared by performing a Gibson approach, which proceeds between the gluteus medius and maximus (FIG 4C,D).
- The Gibson approach may result in less hip extensor dysfunction but may make anterior exposure more difficult.
- A Z-shaped capsulotomy is made to allow entry to the hip joint while protecting the deep branch of the MFCA (FIG 4E).2

FIG 3 • A–C. The patient is positioned full lateral on a pegboard. Before patient preparation, the surgeon should ensure that the leg can be flexed and adducted fully and is not blocked by the anterior inferior peg. D. Position of the leg in the sterile leg holder after dislocation. The hip is flexed, adducted, and externally rotated.
**SURGICAL HIP DISLOCATION BY A TRANSTROCHANTERIC APPROACH**

**Approach to Hip Capsule**

- A longitudinal lateral incision is made, centered over the junction between the anterior and middle thirds of the greater trochanter (TECH FIG 1A).
- The fascia lata is split distally in line with the incision. The proximal dissection progresses through the interval between the anterior edge of the gluteus maximus and the tensor (TECH FIG 1B).
- The proximal 4 to 5 cm of fascia of the vastus lateralis is incised and the vastus muscle fibers are reflected anteriorly.
- The gluteus maximus, along with the fascia of the gluteus medius, which is left on the undersurface of the gluteus maximus for protection, is reflected posteriorly to expose the gluteus medius and insertion.
- A 1- to 1.5-cm-thick trochanteric osteotomy is made with an oscillating saw, leaving the piriformis tendon and

**FIG 4 • A,B.** The trochanteric osteotomy with the attached vastus lateralis and gluteus medius. The tendon of the piriformis (arrow) remains attached to the stable trochanteric base. C,D. The Kocher-Langenback approach splits the gluteus maximus while the Gibson approach spares the gluteus maximus by using the plane between it and the gluteus medius. E. Path of the Z-shaped capsulotomy (solid line). The limb along the posterior aspect of the acetabulum protects the entry of the terminal branches of the medial femoral circumflex artery (white dashed line) and allows access to the hip joint and femoral head (black dashed line).
short external rotators intact on the remaining base of the greater trochanter (TECH FIG 1C).
- The fascia overlying the piriformis tendon is incised to identify the tendon and the interval between the piriformis and capsular minimus muscles (TECH FIG 1D).
- The trochanteric wafer is next reflected and flipped anteriorly with its attached sleeve of vastus lateralis and the gluteus medius (TECH FIG 1E).
- The capsular minimus is elevated in an anterior direction off the hip capsule by carefully dissecting in the interval between the posterior edge of the capsular minimus and the piriformis tendon (TECH FIG 1F).
- An assistant may use a right-angled retractor to assist with the exposure of the capsule.

- Progressive hip flexion, external rotation, and adduction further aid the exposure.
- The hip capsule is exposed up to the rim of the acetabulum.

**Hip Arthrotomy and Dislocation**

- A Z-shaped capsulotomy is then performed, with the longitudinal arm of the Z in line with the anterior neck of the femur.
- The distal arm of the capsulotomy extends anteriorly well proximal to the lesser trochanter.
- The proximal arm is extended posteriorly along the acetabular rim, just distal to the labrum and well proximal to the retinacular branches of the MFCA.

**TECH FIG 1**

- A. The proposed incision after the patient is prepared and draped. B. The Gibson approach is between the gluteus maximus and medius. Note the trochanteric branches of the medial femoral circumflex artery on the greater trochanter (black arrow). C. The trochanteric osteotomy is made with an oscillating saw. D. The fascia over the piriformis tendon (bottom arrow) is divided to develop the interval between it and the capsular minimus (top arrow). E. A 1- to 1.5-cm trochanteric wafer is lifted anteriorly with the gluteus medius and vastus lateralis left attached. F. The anterior capsule is completely exposed before the arthrotomy is made.
entering the capsule posteriorly to supply the femoral head (TECH FIG 2).

- Depending on the pathology, the hip is brought through a range of motion to determine areas of impingement in a dynamic fashion.
- The leg is then placed in the sterile side bag, flexed, externally rotated, and adducted while the hip is subluxated anteriorly through the arthrotomy.
- A bone hook placed around the anterior femoral neck may be needed to subluxate the hip.
- The ligamentum teres is then divided using curved meniscus scissors to allow full dislocation of the hip.

**Dynamic Assessment and Osteoplasty**

- The entire femoral head and acetabulum can now be assessed for chondral flaps or labral tears, which can be repaired using suture anchors spaced about 7 to 10 mm apart or débrided.
- The aspherical segment of the femoral head at the head–neck junction can be resected using a quarter-inch osteotome and rongeur (TECH FIG 3A,B).
- After re-establishing sphericity of the femoral head, the hip is reduced and the results of the débridement are assessed by bringing the hip through a range of motion and confirming the relief of impingement and improvement in range of motion.
- Intraoperative fluoroscopy showing a lateral of the hip in 90 degrees of flexion will determine if the femoral head–neck offset has been re-established (TECH FIG 3C).

**Osteotomy Fixation**

- The trochanteric wafer is reduced and held in position with a towel clip.
- Three 3.5-mm small fragment screws are placed to secure the trochanter. Fluoroscopy confirms reduction and fixation of the osteotomy (TECH FIG 4).
POSTOPERATIVE CARE

- The hip is held flexed and in neutral rotation by placing two pillows under the leg and one under the greater trochanter.
- The patient is placed in a continuous passive motion machine for 6 hours a day, set from 30 to 80 degrees of flexion.
- Prophylaxis for deep venous thrombosis is individualized; however, all patients should be started on mechanical compression devices immediately.
- After the epidural is removed, out-of-bed ambulation is permitted with one-sixth body weight partial weight bearing.
- Range-of-motion exercises are started, but care is taken to protect the greater trochanter osteotomy by limiting adduction to midline, and avoiding resisted abduction exercises for 6 weeks.
- Some patients may benefit from heterotopic ossification prophylaxis using indomethacin.
- AP view of the pelvis or hip and true lateral hip radiographs are obtained 6 weeks postoperatively. Weight bearing is increased to full and hip-strengthening exercises are prescribed.

OUTCOMES

- Ganz \(^1\) has performed over 1200 surgical hip dislocations with no cases of osteonecrosis reported.
- Generally, outcomes are excellent if the correct pathology is addressed in a joint without significant pre-existing arthrosis.
- In a clinical assessment in adults by Murphy et al \(^8\) using the Merle d’Aubigne scale, hip scores improved significantly.

COMPLICATIONS

- Avascular necrosis of the femoral head can occur if care is not taken to follow the technique and to preserve the retinacular vessels.
- Femoral neck fracture if the femoral head-neck junction is aggressively debrided
- Sciatic or femoral nerve neurapraxia
- Greater trochanteric nonunion
- Heterotopic ossification
- Repeated labral tear
- Continued arthrosis of the joint
REFERENCES

DEFINITION
- Coxa vara is a deformity of the proximal femur associated with a neck–shaft angle (NSA) of less than 110 degrees.\textsuperscript{12}
- Developmental coxa vara, also referred to as cervical or infantile coxa vara, is not present at birth, but rather develops in early childhood.
  - This is a rare disease entity with a worldwide incidence of 1 in 25,000 live births.
  - This form has not been connected to an increased association with other musculoskeletal abnormalities.
  - The varus deformity does frequently progress with time.
  - This entity must be distinguished from other forms of coxa vara, such as congenital or acquired.
  - As opposed to developmental coxa vara, the congenital form is present at birth. It is presumed to be caused by an embryonic limb bud abnormality, is associated with an increased incidence of musculoskeletal abnormalities and significant limb-length discrepancy (LLD), and shows minimal progression with growth.
  - The acquired forms of coxa vara are secondary to underlying disorders (eg, metabolic, traumatic, tumors).

ANATOMY
- Growth of the proximal femur occurs at the proximal femoral physeal plate, the femoral neck isthmus, and the greater trochanteric apophysis.
  - The growth at these sites determines the size and shape of the proximal femur, specifically the length of the proximal femur and the NSA.
  - Any injury to the proximal physis will result in a varus deformity owing to continued growth of the femoral neck and trochanter.\textsuperscript{4}
  - Between 3 and 6 months of age, the capital femoral epiphyseal ossification center may be seen.
  - The trochanteric secondary center of ossification begins to ossify at 4 years of age.
  - The NSA normally progresses to a more varus position with growth, starting at approximately 150 degrees at birth and finishing near 120 degrees at full maturity.

PATHOGENESIS
- The exact cause of developmental coxa vara is unknown.
  - An attractive theory, proposed by Pylkkanen,\textsuperscript{8} postulates that the varus deformity is due to a primary ossification defect in the medial femoral neck that results in a more vertical physis.
  - Dystrophic bone forms on the medial aspect of the femoral neck.
  - The physiologic shearing stresses that occur during weight bearing fatigue the dystrophic bone in the medial femoral neck, resulting in progressive varus.\textsuperscript{8}
  - Biopsies of the proximal femoral physis reveal findings similar to those seen in the proximal tibia in patients with Blount’s disease or the proximal femoral physis in patients with metaphyseal chondrodysplasia (Schmid type),\textsuperscript{6} revealing an enlarged growth plate with disorganized islands of cartilage in relatively reduced numbers.\textsuperscript{1,3,8}
  - No evidence of osteonecrosis was seen.

NATURAL HISTORY
- As described by Weinstein et al,\textsuperscript{12} the most reliable factor for progression is the Hilgenreiner–epiphyseal angle (HEA), measured between the line of Hilgenreiner and a line parallel to the proximal femoral physis (FIG 1).
  - Patients whose HEA is more than 60 degrees will invariably progress.
  - The increased varus and retroversion can cause a cam-type impingement.
  - This will then lead to premature degenerative arthritis with progressive pain and disability.
  - If left untreated, the decreased NSA may eventually create too great a strain on the femoral neck, leading to a stress fracture of the femoral neck and eventual nonunion.
  - Patients with an HEA between 45 and 60 degrees have a less defined prognosis and must be followed for progression of varus deformity or increased symptoms.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Developmental coxa vara is typically discovered sometime between the initiation of ambulation and 6 years of age.\textsuperscript{5,7}
- Patients commonly present with a progressive painless limp.
- Pain is an uncommon finding.
If a unilateral abnormality is present, the limp will be due to abductor weakness, as well as a minor LLD (usually less than 2.5 cm).

When present bilaterally, the patient will present with a waddling gait associated with increased lumbar lordosis, similar to what is seen in ambulatory children with bilaterally dislocated hips.

As opposed to patients with dislocated hips, however, no telescoping or signs of instability should be noted.\(^5,8,10\)

The greater trochanter may be prominent and elevated.

Because the abductors are not at their optimal length, they will eventually weaken, leading to easy fatigability and muscle aching.

Abductor weakness may also lead to the development of a Trendelenburg gait.

Hip motion is typically limited (mostly abduction and internal rotation).

Additionally, hip flexion may be restricted secondary to impingement.

Physical examination should include several range-of-motion tests.

Passive abduction: Varus deformity may lead to decreased ability to abduct. Normal full abduction is 40 degrees.

Passive internal rotation: Decreased internal rotation may be secondary to retroversion or impingement.

Internal rotation is variable, but at least 20 degrees is expected.

Passive flexion: Loss of flexion may result from femoroacetabular impingement. Normal full flexion is 120 degrees.

A positive Trendelenburg sign—tilting of the pelvis down toward the nonstance leg—indicates abductor weakness.

LLD may indicate growth disturbance of the proximal femur.

### IMAGING AND OTHER DIAGNOSTIC STUDIES

Evaluation consists primarily of an AP radiograph of the pelvis (FIG 2A).

- The NSA is substantially decreased, often less than 90 degrees.
- The proximal femoral physis is wider and more vertical, with a triangular metaphyseal fragment in the inferior neck surrounded by physis, giving an inverted Y pattern—the sine qua non of developmental coxa vara.
- Also notable are decreased femoral anteversion, coxa breva, and possible mild acetabular dysplasia.

A frog-leg lateral radiograph (FIG 2B) as well as a CT (FIG 2C,D) or MRI may also be obtained to provide more information.

### DIFFERENTIAL DIAGNOSIS

- Congenital coxa vara
- Proximal femoral focal deficiency
- Skeletal dysplasia
  - Cleidocranial dysostosis
  - Metaphyseal dysostosis (Jansen type)
  - Spondylometaphyseal dysplasia (Kozlowski type)
Avascular necrosis
- After reduction for developmental hip dislocation
- Trauma (femoral neck fracture or hip dislocation)
- Septic joint
- Slipped capital femoral epiphysis
- Pathologic bone condition
  - Fibrous dysplasia
  - Osteogenesis imperfecta
  - Renal osteodystrophy
  - Osteopetrosis

**SURGICAL MANAGEMENT**

Patients with an HEA greater than 60 degrees are candidates for surgical intervention, as are patients with an HEA greater than 45 degrees who are symptomatic (limp or progressive deformity).

**Preoperative Planning**

- Clinically assess range of motion (ROM) and LLD.
- Review all images.
- Determine the desired alignment (version, NSA, offset).
- Choose implant type based on patient age and size.
- Kirschner wire: for dwarves or children up to 4 years of age with bones too small for a plate
- Custom-made high-angle blade plate: used for older children with bones too large for the Kirschner wire technique
- Wagner plate: an alternative plate for patients with bones too big for the Kirschner wire technique when a custom-made high-angle blade plate is not accessible

**Positioning**

- The patient is supine on a radiolucent table with a folded blanket beneath the pelvis.
- This elevation allows more room for movement, especially when working posteriorly or when trying to drop your hand to aim anteriorly.

**Approach**

- The standard lateral approach to the proximal femur is used.

**EXPOSURE**

- The fascia lata is split longitudinally.
- The vastus lateralis fascia is incised longitudinally about 5 to 10 mm anterior to the intermuscular septum and is elevated atraumatically from the femur.
- This muscle is then released proximally from the femur with a transverse incision just below the level of the greater trochanteric apophysis.
- The periosteum is incised along the anterolateral femur and subperiosteal dissection is performed circumferentially just proximal to the level of the lesser trochanter.
- The anterior neck is visualized to assess femoral version.
- The bone is scored longitudinally with an electrocautery or saw, or Kirschner wires can be placed proximal and distal to the osteotomy site to assess rotation after the osteotomy has been performed.

**VALGUS OSTEOTOMY USING MULTIPLE KIRCHNER WIRE FIXATION**

- Three Kirschner wires (7/64-inch are most common) are inserted in parallel (TECH FIG 1A), lined up in a transverse fashion, up the middle of the neck.11,13
- The lateral cortex is entered 5 to 10 mm distal to the trochanteric apophysis, and the wires are directed up the neck in parallel and advanced into the femoral head.
- Starting more proximally allows for more lateralization of the femoral shaft.
- The starting point may be more anterior if there is increased retroversion.
- The three Kirschner wires are then bent to the desired angle of correction determined preoperatively (typically about 160 degrees) and rotated proximally to be out of the way (TECH FIG 1B,C).
- An additional Kirschner wire is inserted at the level of the lesser trochanter perpendicular to the shaft to act as a guide for the osteotomy.
- A bone tenaculum is placed on the greater trochanter to allow for control of the proximal fragment after the osteotomy.
- Two bone cuts are made parallel to the Kirschner wire, about 5 mm on either side of the wire, and then this cylindrical segment is removed (TECH FIG 1D).
- This allows for some shortening to relieve pressure on the femoral head and to reduce medial soft tissue tension.
- The thick medial periosteum must be divided to allow for valgus correction and lateralization of the shaft.
- The lateral cortex of the proximal fragment is abraded with the saw or with a burr to promote healing.
- Trial reduction is attempted by gently pushing down on the Kirschner wires (without stressing the Kirschner wires to prevent pullout) to adduct the proximal fragment while abducting and translocating the distal fragment.
- The three Kirschner wires are then rotated distally and brought down to the shaft so that the lateral cortex of the proximal fragment lies on or is impacted into the proximal end of the distal fragment (TECH FIG 1E).
- The fragments are temporarily stabilized by holding down the Kirschner wires to the lateral cortex of the distal fragment with a Verbrugge clamp.
- An interfragmentary Kirschner wire may be inserted for added stability.
- The Kirschner wires are then definitively secured to the shaft with a cerclage wire, a small semitubular plate, or both.
- The vastus lateralis should be sutured securely to the greater trochanter to provide a lateral tension band.
VALGUS OSTEOTOMY USING WAGNER PLATE FIXATION

- A Kirschner wire is inserted just proximal to the proposed insertion site parallel to the planned angle of the plate.
- The 115-degree Wagner plate is impacted through the lateral cortex of the femur, starting just above the level of the trochanteric apophysis and aiming toward the inferior aspect of the neck, at a preoperatively determined angle (TECH FIG 2).
  - Starting more proximally allows for more lateralization of the femoral shaft.
- A Kirschner wire is inserted at the level of the lesser trochanter perpendicular to the shaft to act as a guide for the osteotomy.
- A bone tenaculum is placed on the greater trochanter to allow for control of the proximal fragment after the osteotomy.
- Two bone cuts are made parallel to the Kirschner wire, about 5 mm on either side of the wire, and then this cylindrical segment is removed.
  - This allows for some shortening to relieve pressure on the femoral head.
- The thick medial periosteum must be divided to allow for valgus correction and lateralization of the shaft.
- Reduction should be attempted without stressing fixation (prevents pullout).
- The lateral cortex of the proximal fragment is abraded with the saw or with a burr to promote healing.
- The plate is then brought down to the shaft so that the lateral cortex of the proximal fragment lies on or is impacted into the end of the distal fragment and is secured with two screws.
- An interfragmentary screw may be inserted for added stability.
- The vastus lateralis should be sutured securely to the greater trochanter to provide a lateral tension band.

TECH FIG 2 • Wagner plate fixation. Insertion of the plate parallel to the proximal guidewire.
VALGUS OSTEOTOMY USING ADOLESCENT BLADE PLATE FIXATION

- A Kirschner wire is inserted just proximal to the proposed insertion site parallel to the planned angle of the plate.
- The blade plate chisel is impacted through the lateral cortex of the femur, starting just above the level of the trochanteric apophysis and aiming toward the inferior aspect of the neck, at a preoperatively determined angle.
  - Starting more proximally allows for more lateralization of the femoral shaft.
- A Kirschner wire is inserted at the level of the lesser trochanter perpendicular to the shaft to act as a guide for the osteotomy.
- A bone tenaculum is placed on the greater trochanter to allow for control of the proximal fragment after the osteotomy.
- Two bone cuts are made parallel to the Kirschner wire, about 5 mm on either side of the wire, and then this cylindrical segment is removed.
- This allows for some shortening to relieve pressure on the femoral head.
  - The thick medial periosteum must be divided to allow for valgus correction and lateralization of the shaft.
  - Reduction is attempted without stressing the plate (prevents pullout).
  - The lateral cortex of the proximal fragment is abraded with the saw or with a burr to promote healing.
  - The plate is then brought down to the shaft so that the lateral cortex of the proximal fragment lies on or is impacted into the end of the distal fragment and is secured with screws.
  - An interfragmentary screw may be inserted for added stability.
  - The vastus lateralis should be sutured securely to the greater trochanter to provide a lateral tension band.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Implant choice</th>
<th>The Kirschner wire technique should be used for patients with smaller bone, who would not be able to accommodate a larger plate.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Positioning</td>
<td>Placing a folded blanket beneath the pelvis to elevate the patient off the bed allows more room to maneuver.</td>
</tr>
<tr>
<td>Instrumentation placement</td>
<td>Insertion of the fixation device more proximally in the proximal fragment allows for more lateralization of the femoral shaft.</td>
</tr>
<tr>
<td></td>
<td>Insertion more anteriorly accounts for any retroversion of the neck.</td>
</tr>
<tr>
<td>Achievement of correction</td>
<td>Removal of a segment of bone allows for less soft tissue tension so that the valgus correction can be achieved and the risk of implant failure can be minimized.</td>
</tr>
<tr>
<td></td>
<td>Dividing the thick medial periosteum allows more freedom of motion to achieve valgus correction and lateralization of the shaft.</td>
</tr>
<tr>
<td>Avoiding pullout</td>
<td>An initial reduction should be attempted without placing pressure on the fixation device to avoid pullout.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Radiographs are evaluated to ensure that instrument placement and alignment are appropriate.
- The child is placed in a well-padded spica cast for 4 to 6 weeks or until bony healing is evident.

OUTCOMES

- If adequate valgus is achieved, the triangular defect will spontaneously close by 3 to 6 months after surgery in nearly all patients.5
- Fifty percent to 89% of operated hips sustain a premature closure of the proximal femoral physeal, which occurs 1 to 2 years postoperatively and has not been found to correlate with patient age, surgical trauma, or degree of valgus.15
- Recurrence has been reported in 30% to 70% of patients, though correction of the HEA to less than 38 degrees has been shown to have a 95% success rate.2
- These patients must be monitored for recurrent varus deformity or significant LLD that may require further surgical intervention.

COMPLICATIONS

- Recurrence
- Proximal femoral physeal closure
- Avascular necrosis
- Implant failure
- Infection

REFERENCES

DEFINITION
- Valgus osteotomy for Legg-Calvé-Perthes disease (Perthes disease) is a salvage operation. It is designed for those hips in which the primary goal of containment is no longer possible owing to hinge abduction. The following sections are focused on hips that have developed hinge abduction rather than a complete discussion of Perthes disease.
- The valgus osteotomy relieves the hinging and improves congruency of the hip joint.

ANATOMY
- A femoral head with normal anatomy moves concentrically within the acetabulum. The lateral aspect of the femoral head glides under the acetabulum with abduction.
- In severe Perthes disease with significant deformity of the femoral head, the lateral aspect of the head may impinge on the acetabulum with attempted abduction. Continued abduction creates a lateral hinge, which pulls the inferomedial portion of the head away from the acetabulum.4

PATHOGENESIS
- Hinge abduction is a consequence of several contributing factors.
- Early in the process of Perthes disease there is cartilaginous overgrowth laterally and anteriorly. Later, during the healing process, this cartilage ossifies, contributing to the ridge of lateral bone.
- Osteonecrosis of the bony epiphysis of the femoral head leads to recurrent subchondral fractures.
- These fractures are associated with a loss of epiphyseal height and a change in shape from round to oval.
- Fragmented portions of the epiphysis may be extruded laterally.
- With collapse, the femoral head migrates proximally and laterally, progressively uncovering the lateral aspect of the femoral head.
- Catterall’s description of “head at risk signs” identified four radiographic findings associated with the later development of hinge abduction.2
  - A lytic area on the lateral aspect of the epiphysis known as Gage’s sign3
  - Calcification lateral to the epiphysis
  - Lateral subluxation of the femoral head
  - A horizontal orientation of the physeal line (as opposed to the normal more medial inclination)
- Hinge abduction is also seen in osteonecrosis of other causes but is commonly associated with Perthes disease.

NATURAL HISTORY
- At maturity, patients with unrelieved hinge abduction would generally be classified as Stulberg category IV (flattened femoral head with a round acetabulum), both of which have been found to be associated with early-onset osteoarthritis.5
- Patients with hinge abduction often develop pain in the second decade of life.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically have pain with activity that is relieved by rest.
- The most notable physical finding is limited abduction of the hip. Often the patients are unable to abduct the hip to neutral. Attempted abduction is painful.
- There is generally 1 to 2 cm of shortening.
- Patients walk with an antalgic gait with the hip in adduction.
- A positive Trendelenburg sign indicates weakness of the hip abductor mechanism, which is unable to stabilize the pelvis.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Gross hinge abduction may be visualized on plain radiographs (FIG 1A,B).
- On arthrogram, visualization of pooling of dye medially with abduction of the hip is considered diagnostic. The arthrogram is studied in anteroposterior (AP) and lateral projections with abduction, adduction, and internal and external rotation to determine the position that maximizes congruency and relieves impingement (FIG 1C,D).

DIFFERENTIAL DIAGNOSIS
- Impingement from relative trochanteric overgrowth
- Subchondral fracture

NONOPERATIVE MANAGEMENT
- Perthes disease often does not require any intervention.
- Treatment strategies early in the course of the disease should focus on containment of the femoral head in the acetabulum and preservation of the range of motion.
- Patients with hinge abduction have pain with activity.
- If hinge abduction is seen on radiographs but the patient is symptom-free, an osteotomy would still improve the prognosis. In that scenario it would be reasonable to wait until the patient is symptomatic.

SURGICAL MANAGEMENT
- The valgus osteotomy is considered a salvage operation for late cases in which the femoral head has developed a lateral ridge that can no longer be brought under the acetabulum.

Preoperative Planning
- The arthrogram is reviewed. Extension, flexion, or rotation may be required in addition to valgus to fully relieve impingement and maximize congruency.
Preoperative templating is essential.

- The template is rotated into abduction to check for lateral impingement.
  - The amount of valgus required to allow at least 10 degrees of abduction without lateral impingement is measured. Usually about 20 degrees of correction is required.
  - The oblique limb of the osteotomy should be just below the lesser trochanter.
  - Placing the transverse limb distally will bring the completed osteotomy parallel to the ground when the patient is standing.

Fixation should also be drawn on the template.

- I prefer a 120-degree blade plate with a lateral stepoff, which provides medialization of the distal fragment (FIG 2).
- The placement of the blade plate, rather than the saw cuts, will dictate the final position of the osteotomy.

To calculate the angle for insertion of the blade plate relative to the femoral shaft, the angle of the planned correction is subtracted from 120 degrees.

- Example: For a desired 20 degrees of valgus correction, the blade is inserted at 100 degrees from the shaft. With the blade at 100 degrees, the shaft must come into 20 degrees of valgus to accommodate a 120-degree fixed-angle blade plate.

- The blade plate should occupy 50% to 75% of the width of the femoral neck on the lateral projection for optimum strength.

Positioning

- The patient is placed supine on a radiolucent surgical table with a soft bump under the affected hip.
- The surgeon should check that sufficient AP and lateral radiographs can be obtained.

Approach

- The lateral approach to the hip is used.
EXPOSURE

- The fascia lata is split in line with the fibers over the palpated lateral border of the femur.
- The vastus lateralis is elevated from the intermuscular septum. Perforating vessels are identified and cauterized.
- Proximally, the fascia of the vastus lateralis is opened anteriorly with the electrocautery along the vastus ridge, creating an L shape (TECH FIG 1).
- The femur is exposed subperiosteally. The exposure should be extended sufficiently distal to allow removal of the previously measured segment of bone and the application of a plate.

VALGUS OSTEOTOMY OF THE FEMUR USING A CANNULATED BLADE PLATE

Guidewire Placement

- If using a cannulated blade plate (Smith and Nephew, Memphis, TN), a guidewire is inserted in the proposed location for the blade.
- To insert the wire at the proposed angle, a premeasured triangle equal to the supplement of the desired angle of insertion is held against the lateral aspect of the femur.
  - To use the previous example, 180° - 100° = 80 degrees (TECH FIG 2A).
- In the lateral plane, the wire should parallel the proposed track of the blade plate (ie, centered in the femoral neck) (TECH FIG 2B).
- The length of the inserted guidewire is measured.
- The guidewire is inserted further than the templated blade plate depth.

Chisel Insertion

- The chisel is inserted parallel to the guidewire in the AP and lateral planes (TECH FIG 3A).
  - For pure valgus, the chisel is perpendicular to the lateral shaft of the femur (TECH FIG 3B).
  - To add extension or flexion, the chisel is rotated posteriorly or anteriorly from perpendicular, respectively. The desired amount of flexion or extension should be marked on the bone (TECH FIG 3C).
The chisel is frequently backed up during insertion to prevent incarceration.
The path of the chisel is checked periodically with fluoroscopy.
The chisel is backed up to loosen it before making the osteotomy. The surgeon should verify it has backed up by checking the depth measurement.

**Making the Osteotomy**

The proximal limb of the osteotomy should be planned as far distally from the base of the chisel as possible without interfering with the bend of the plate or the most proximal screw hole for plates without offset. This distance is usually just under 10 mm but should be checked for each plate, as systems vary (TECH FIG 4A).
A precut template wedge (a sterilized piece of a soda can works well) is used to mark the angle of the osteotomy.
The length of lateral cortex to be removed is also measured on the preoperative radiographs, but the measurement should be verified intraoperatively.
A longitudinal mark for rotation is made along the femur before making any cuts. The mark should be long enough not to be excised by the osteotomy. The mark should be well anterior to the plate so it will still be visible while the plate is being applied.
The proximal cut is parallel to the chisel in the lateral plane. This holds true whether the goal is pure valgus or valgus with extension–flexion. The distal cut is perpendicular to the shaft of the femur (TECH FIG 4B,C).

**Blade Plate Placement**

When the chisel is removed, it should be exchanged for the blade plate quickly as the proper orientation is easily lost.
The blade plate should be inserted by hand initially to prevent deviation from the desired path.
The distal portion of the femur is reduced to the side plate and secured with a bone-reduction clamp.
Rotation is confirmed using the previously placed orientation line.
The side plate is secured to the femur using standard technique with the initial screws inserted in compression.

**TECH FIG 4 • A.** Angle of limbs of osteotomy in AP plane. The distal cut is transverse. **B.** In pure valgus, the osteotomy cuts are parallel in the lateral plane. **C.** For added extension, cuts are convergent anteriorly. Note proximal limb parallel to chisel in lateral plane.

**VALGUS OSTEOTOMY OF THE FEMUR USING A NONCANNULATED BLADE PLATE**

The technique using a noncannulated blade plate is the same with the exceptions that follow.
With a solid blade plate, the guidewire should be inserted parallel to the proposed course of the chisel (TECH FIG 5A).

The wire should be far enough away so that it does not interfere with the chisel but should be close enough to follow easily.
This technique requires more frequent fluoroscopic images during chisel insertion to be sure the guidewire is being followed in both the AP and lateral planes. When

**TECH FIG 5 • A.** Solid system insert chisel parallel to guidewire.
TECH FIG 5 • (continued) B. Guide arm of chisel is parallel to the femoral shaft for pure valgus. C. Guide arm of chisel parallel to femoral shaft for pure valgus.

PEARLS AND PITFALLS

<tr>
<th>Chisel incarceration</th>
<th>This can be prevented by frequently backing the chisel out.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>The surgeon should be sure it really backs up. Check the markings. It is easy to be deceived.</td>
</tr>
<tr>
<td>Loss of guidewire, cannulated system</td>
<td>This happens when the chisel is inserted past the end of the guidewire.</td>
</tr>
<tr>
<td></td>
<td>The surgeon should check with a radiograph while removing the chisel to verify the guidewire is staying in place.</td>
</tr>
<tr>
<td>Loss of guidewire, noncannulated system</td>
<td>This occurs when the chisel is inserted too close to the guidewire, destabilizing it.</td>
</tr>
<tr>
<td>Chisel insertion measurement</td>
<td>The surgeon should verify before insertion whether the system being used puts the numbers above or below the hashmark (FIG 3).</td>
</tr>
<tr>
<td>Osteotomy reduction, blade plate manipulation</td>
<td>The distal femur should be brought to the blade plate as much as possible. Excessive torque on the blade plate should be avoided.</td>
</tr>
<tr>
<td></td>
<td>The blade may break out of the proximal fragment, especially if insufficient distance was maintained between the bottom of the chisel and the osteotomy.</td>
</tr>
<tr>
<td></td>
<td>Radiographs are obtained before final seating to ensure the guidewire is being followed.</td>
</tr>
<tr>
<td></td>
<td>The surgeon should not attempt to move the leg into position for a lateral radiograph until the blade plate is inserted far enough to be secure. Performing this maneuver before there is adequate purchase will cause the blade plate to break out of the hole.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- Patients are allowed to bear weight as tolerated with crutches. Patients who are expected to be noncompliant with crutches and activity limitations are placed in a single-leg spica cast.
- Elective hardware removal is controversial. I prefer hardware removal 1 to 2 years postoperatively or after bony union is obtained in patients in whom the likelihood of future surgery, including joint arthroplasty, is high.

OUTCOMES

- Three recent publications\(^1\,\,^4\,\,^6\) reported subjectively satisfactory results (by varying standards) in 66% to 94% of patients at 5 to 10 years of follow-up. Average Iowa hip scores ranged from 86 to 93. Further hip surgery had been performed on 10% to 20% of patients.
- Two of the three recent articles noted no significant changes in the Sharp angle and percent coverage.\(^1\,\,^4\) One study noted a
significant difference in the percent coverage and superior joint space.6

- Bankes et al1 reported two factors associated with favorable remodeling, both concerning the timing of surgery: when the osteotomies were carried out during the healing phase of Perthes disease, and when they were carried out in patients with open triradiate cartilages.

COMPLICATIONS

- Nonunion is rare with the osteotomy in the immediate subtrochanteric region. If the osteotomy is created more distally in the diaphyseal bone, nonunion may occur.
- Hardware failure most commonly occurs via the blade plate breaking out of the proximal fragment, when too small of a bone bridge was preserved.
- Valgus osteotomy for Perthes disease is a salvage procedure. The desired outcome is to relieve pain and delay the progression of osteoarthritis. It is important to communicate preoperatively that the progression of osteoarthritis is not prevented.

REFERENCES

Slipped capital femoral epiphysis (SCFE) is a common hip disorder in adolescents in which the neck and femur displace anterolaterally (most commonly into varus and extension) with respect to the proximal femoral epiphysis. SCFE can be classified as stable or unstable. A child with a stable SCFE has pain and a possible limp but is able to bear weight, whereas a child with an unstable SCFE is unable to bear weight even with crutches. A stable slip has a nearly 0% risk of osteonecrosis, but an unstable slip has a 50% risk of osteonecrosis.

SCFEs have also been described by duration of symptoms as chronic (greater than 3 weeks of symptoms), acute (less than 3 weeks of symptoms), or acute on chronic (longstanding mild symptoms with an increase in symptoms of less than 3 weeks’ duration). This latter classification correlates less well with the risks of avascular necrosis (AVN) and chondrolysis.

The proximal femoral physis and epiphysis are located within the hip capsule. Although the proximal physis provides length and shape to the femoral neck, most SCFEs occur in adolescence, when little growth remains at this growth plate. The blood supply to the proximal femoral epiphysis comes from the medial femoral circumflex artery, which travels along the femoral neck. From the circumflex arise the lateral epiphyseal vessels, which enter the epiphysis posterosuperiorly. Small contributions come from the vessels of the round ligament and the posterior inferior epiphyseal vessels off the medial femoral circumflex artery. Injury to this tenuous capsular blood supply can result in osteonecrosis.

In SCFE, the epiphysis stays within the acetabulum while the neck and distal femur slip (most commonly into extension and varus).

SCFE occurs more commonly in boys than girls (60% of patients are boys). Most patients (up to 75%) are adolescents (boys 13.5 years, girls 12.0 years on average). Most patients are obese and in the 90th to 95th weight percentile for age. SCFE occurs bilaterally in about 25% of patients.

Biochemical factors likely play a role. Hormonal changes that occur during adolescent growth influence the strength of the physis.

Biomechanical factors also likely play a role. The physis in SCFE is subjected to higher shear force. The physis is more oblique during adolescence and in obese children; both factors increase shear in normal activities. The proximal femur is relatively retroverted in many cases of SCFE, which also increases the shear force on the physis. The reinforcing perichondral ring of the proximal physis also weakens with age until growth plate closure.

If the physis of a SCFE patient is studied histologically, it will look widened, with abnormal chondrocyte maturation and endochondral ossification. The slip occurs mainly through the hypertrophic zone of the physis.

Patients under age 10 years should be evaluated for an underlying endocrine abnormality, including hypothyroidism, renal osteodystrophy, and panhypopituitarism.

The natural history of untreated SCFE and the ultimate outcome are difficult to predict, although it is widely accepted in adult reconstructive circles that most cases of degenerative hip arthritis are secondary to an underlying structural cause, such as SCFE. The risk of progression exists while the physis remains open. The slip severity increases with the duration of symptoms.

The development of degenerative joint disease is related to the severity of the slip.

Physical examination methods include the following:

- The resting position of the knee and foot is observed with the patient lying supine and it is compared to the other side. Excessive external rotation is a result of the slip.
- Hip range of motion (ROM) between affected and normal sides (for stable SCFE only) is compared. Because of slip, the affected side has decreased flexion, abduction, and internal rotation of the hip. There may be guarding with ROM.
- In SCFE that presents with knee pain, passive knee ROM is normal and effusion is absent.
- In stable SCFE, the patient has an antalgic gait. The foot may be externally rotated. In unstable SCFE, the patient is unable to bear weight at all on the affected side.
- Patients complain of hip or groin pain, thigh pain, or knee pain, which may be exertional and usually occurs without a history of trauma.
- The patient may have a limp (stable slip) or frank inability to bear weight (unstable slip).
- Examination of the hip can reveal an externally rotated foot and knee, guarding of the hip with ROM, and decreased flexion and internal rotation of the hip.
- Findings on the knee examination are normal.

Plain radiographs of the pelvis, including anteroposterior (AP) and frog-leg lateral views, should be obtained in any pediatric patient with hip, thigh, or knee pain.

A widened physis on AP or lateral views can be an early sign of SCFE.

The Klein line, which can demonstrate SCFE, is drawn along the neck of the femur, superiorly on the AP view. In a
normal hip, this line should intersect the epiphysis, but in SCFE it will not cross the epiphysis (FIG 1).
- The metaphyseal blanch sign of Steel is a crescent-shaped double density along the medial femoral neck where the slipped epiphysis overlaps the metaphysis on the radiograph.
- Images of the contralateral hip should be scrutinized for evidence of bilateral SCFE. If present, both sides should be treated.
- The severity of a SCFE can be described by displacement relative to the width of the metaphysis:
  - Mild: Less than one-third the width
  - Moderate: One-third to half the width
  - Severe: More than half the width
- Another method of describing slip severity is measuring the difference between the epiphyseal shaft angle on each side:
  - Mild: Less than 30 degrees
  - Moderate: 30 to 50 degrees
  - Severe: 50 degrees or greater
- If the patient is under 10 years of age, underlying endocrine abnormalities should be investigated with laboratory studies, including thyroid function tests and basic chemistries.

**DIFFERENTIAL DIAGNOSIS**
- SCFE
- Legg-Perthes disease
- Hip labral tear
- Femoral neck stress fracture
- Septic arthritis of the hip
- Knee derangement
- Greater trochanteric bursitis

**NONOPERATIVE MANAGEMENT**
- Immobilization in a spica cast was the historical treatment but is no longer recommended for SCFE.
- Once SCFE is identified in any patient with an open physis, management is surgical to avoid further slippage and the possible development of femoral head AVN.

**SURGICAL MANAGEMENT**
- When SCFE is identified in a patient with an open physis, surgical management with percutaneous in situ cannulated screw fixation should be undertaken on an urgent basis if the slip is stable or on an emergent basis if unstable. There is a fair amount of evidence that the risk of AVN in unstable SCFE can be reduced if the hip is decompressed in some manner within 24 hours.
- Before surgery, the patient should remain strictly non-weight bearing on the affected leg.
- In unstable SCFE, reduction of the displacement is controversial. Reduction has been associated with osteonecrosis, but the unstable slip itself may be the more likely cause of osteonecrosis.
  - Because of the risk of contralateral slip, prophylactic pinning of the contralateral hip should be considered and discussed with the patient and family, especially if the patient is under age 10 or has an endocrine abnormality.

**Preoperative Planning**
- All imaging studies are reviewed. The plain films of the contralateral hip should be scrutinized for evidence of early or clinically silent slip.
- Laboratory studies should be reviewed in patients under 10 years of age.

**Positioning**
- We place the patient supine on the radiolucent OR table with the entire affected leg prepared and draped free to the umbilicus. The ipsilateral arm is padded and positioned across the chest.
- The fluoroscopy monitor is placed at the patient’s head and the C-arm unit is positioned for AP views of the hip from the contralateral side of the operating table. The hip is flexed 90 degrees and abducted 45 degrees to obtain lateral views. Not using a fracture table allows multiple views to be sure that the guide pin and the bone screws do not penetrate the femoral head.
- Some surgeons prefer to perform in situ screw fixation on a fracture table.

**Approach**
- In situ cannulated screw fixation of SCFE involves placement of the guidewire into the central third of the epiphysis perpendicular to the physis. This is followed by drilling and placement of the screw over the guidewire. Some screws are self-tapping and self-drilling.
- Careful examination of spot fluoroscopy images ensures that the screw tip is within the femoral head, as detailed in the Techniques section.
GUIDEWIRE PLACEMENT

- The goal of guidewire placement is to place the tip of the wire perpendicular to the physis in the middle third of the epiphysis, about 3 mm from the subchondral bone. Spacing of the screw threads can be measured (usually 1 mm) and compared on the image intensification screen as a ruler. For the most common SCFE (varus slip), the starting point is on the anterior neck to place the wire properly in the middle of the epiphysis.

Determining the Course of the Guidewire

- Under image guidance (AP view with the image machine placed vertical), the hip is internally and externally rotated until the neck appears to be its longest. At this position of rotation, the femoral neck is horizontal to the operating table and perpendicular to the image beam (TECH FIG 1A).
- A guidewire is placed on the anterior hip and image intensification is used to align the point of the wire over the center of the femoral head. The guidewire is then aligned along the neck (TECH FIG 1B). The skin is marked at the tip to identify the position of the center of the femoral head.
- The marker then follows the guidewire laterally to the lateral aspect of the femur. This line represents the course along which the guide pin for the bone screw will follow in the AP image (TECH FIG 1C). The marked line is drawn with a pen (TECH FIG 1D).

Determining the Entry Point Along the Femoral Neck

- While we know that the femoral neck is following this marked line, the position of the femoral head in the sagittal plane is determined by flexing the hip 90 degrees and abducting the hip 45 degrees. A line is drawn on the image as a diameter of the femoral head, and then a line is drawn perpendicular to the diameter at its center representing the desired path of the bone screw in the sagittal plane (TECH FIG 2A). The angle this line makes with the femoral neck tells the position of the femoral head with respect to the end of the femoral neck. The position this line crosses the femoral neck line also defines the entry point for the guide pin along the femoral neck (TECH FIG 2B,C). The degree of slip of the epiphysis posteriorly with respect to the neck is estimated.
- Having taken the steps above, the surgeon has now determined how to make the femoral neck horizontal to the operating table and perpendicular to the image beam and has determined the angle that the femoral head is with respect to the end of the femoral neck and the entry point on the anterolateral neck for the guide pin and screw.

Determining the Skin Entry Site

- The final issue for the surgeon to determine is where to enter the skin. The skin is like a circle around the hip. The

TECH FIG 1 • Patient is supine on the operating table. A. The image intensifier is set for an AP view and an image is obtained. The hip to be operated on is rotated internally and externally until the length of the neck appears longest. The femoral neck is now horizontal. This position is maintained. B. A long guidewire is placed on the patient at the hip with the point centered on the center of the femoral head and the guidewire over the center of the neck. C. This is confirmed with an image view. D. An OR pen is used to mark the skin with this line. The femoral shaft is palpated laterally on this line; this point is marked as 0 degrees. The point over the femoral head is marked as 90 degrees. (A,C: Copyright Richard S. Davidson, MD.)
Mark for the center of the femoral head is at 90 degrees and the lateral (palpable) femoral shaft is at 0 degrees (TECH FIG 3A). If the head–neck angle measured is, for example, 30 degrees, the entry point on the skin should be 30 degrees from the lateral palpable femoral shaft toward the femoral head.

Helpful hint: This position can be obtained by taking a length of suture that goes from the femoral head mark to the lateral femur mark (representing 90 degrees) and dividing it into thirds (30 degrees). The surgeon then measures from the lateral femoral shaft (0-degree mark) toward the head along the drawn line.

Tech FIG 2 • The hip is flexed 90 degrees and abducted 45 degrees. A. An AP image is obtained. B. The image shows the femoral neck and the displaced femoral head. C. The neck-to-head angle is measured, and the point at which a line through the center of the head and perpendicular to the physis intersects the neck is noted. This is the entry point for the guide pin and bone screw. (A: Copyright Richard S. Davidson, MD.)

Tech FIG 3 • A. The hip is then returned to the “neck horizontal” position. B. A 1-cm incision is made along the drawn line at the number of degrees from the lateral femur (0 degrees). The fascia is spread with a clamp. C. The guide pin is inserted into this incision along the marked line but at the measured neck–head angle. The level of insertion at the neck is at the point observed in Techniques Figure 2C. (C: Copyright Richard S. Davidson, MD.)
A 1-cm incision is made through skin and spread with a hemostat down to bone along the drawn line, but at an angle of 30 degrees toward the horizontal (ie, the head–neck angle) (Tech Fig 3B).

The guide pin should enter the incision in line with the drawn line and at an angle of 30 degrees to the horizontal (Tech Fig 3C). The point of the guide pin should be positioned on the anterolateral femoral neck where the entry was estimated above.

**Inserting the Guidewire**

- The guide pin is drilled into the femoral neck to the mid-neck and then additional image views are taken to confirm and fine-tune the position. When satisfactory, the guide pin is drilled to within 3 mm of the articular surface and measured, and a bone screw is chosen. Multiple image views should confirm the guide pin position before inserting the bone screw to avoid stress risers from too many holes in the bone.
  - Helpful hint: The surgeon can rotate the hip to prevent bending of the guide pin while flexing to get multiple views.
  - The chosen bone screw is inserted to within 3 mm of the articular surface.
  - Helpful hint: If the end of the guide pin is threaded, the bone screw may advance the guide pin through the articular surface. The hip must not be moved because of the risk of breaking off the end of the guide pin in the hip joint. Instead, the surgeon can retract the guide pin partially into the bone screw and then continue to advance the bone screw to the appropriate position. Again, multiple views are obtained to ensure that the bone screw does not penetrate the articular surface.

**Drilling and Cannulated Screw Placement**

- The guidewire is measured with the cannulated depth gauge to determine desired screw length.
- The cannulated drill is drilled over the guidewire. Care is taken to keep the drill colinear with the guidewire to avoid binding. The drill should stop 1 or 2 mm before the tip of the guidewire to keep the guidewire in place.
- The bone is tapped with the cannulated tap over the guidewire.
- The 6.5- to 7.5-mm cannulated screw is placed over the guidewire.
- The guidewire is removed.

**Radiographic Evaluation**

- Radiographic evaluation (Tech Fig 4) ensures good screw position to minimize risk of complications.
- Spot fluoroscopic AP and frog-leg lateral views are used to make sure that four or five threads of the screw are within the epiphysis to decrease the risk of slip progression.
- The approach-and-withdraw technique allows evaluation of the screw tip to ensure that it remains within the femoral head. With live fluoroscopy, the hip is ranged from internal to external rotation at varying degrees of flexion and the screw tip is observed to approach and withdraw from the subchondral bone. The closest point is observed and the screw should remain within the femoral head.9

PEARLS AND PITFALLS

Guidewire placement
- In general, the larger the slip, the more proximal the starting point along the anterior neck.
- The guidewire should be placed into the center of the epiphysis parallel to the physis to obtain maximum fixation, like the handle of an umbrella.

Guidewire bending
- When the hip is moved from resting position to frog-leg lateral position or back again, the quadriceps fascia must be meticulously retracted to prevent guidewire bending.

Guidewire pullout
- Drilling should stop 1 to 2 mm before the end of the guidewire to keep it seated in bone. The surgeon should check spot fluoroscopy as the drill is backed out to make sure the guidewire remains in place.
- The guidewire should be gently tapped back into place if it begins to pull out.

Guidewire binding
- During drilling, tapping, or screw placement, the instrument can bind the guidewire and cause unwanted advancement of the guidewire.
- The cannulated instrument must remain perfectly colinear with the guidewire.
- The surgeon should check spot fluoroscopy to make sure the guidewire is not advancing.

POSTOPERATIVE CARE
- No immobilization in recommended. Patients should remain non-weight bearing or touch-down weight bearing on crutches on the affected leg for about 6 weeks to allow healing.
- Patients are gradually allowed to return to activities after 6 weeks.
- If the SCFE and fixation were unilateral, patients and families must be made aware of symptoms to watch for that could indicate slipping in the other hip, like hip, thigh, or knee pain.
- Patients should be followed at regular intervals until the proximal femoral physis closes completely on radiographs.

OUTCOMES
- Outcomes of SCFE treatment are related to the severity of slip and the development of complications. The best long-term results are seen with in situ screw fixation. In patients with mild and moderate SCFE treated with in situ screw fixation, results are good to excellent.

COMPLICATIONS
- Chondrolysis is articular cartilage necrosis of the femoral head that causes hip pain and limited motion.
  - It has been associated with SCFE and its treatment, and the incidence has decreased with modern treatment techniques of in situ screw fixation.
  - Risk factors include unrecognized pin or screw penetration, spica cast treatment, more severe slips, and female sex. The joint space appears narrowed to less than 3 mm on radiographs, and treatment involves revision of prominent hardware, limited weight bearing until symptoms improve, physical therapy, and nonsteroidal anti-inflammatories.
- Overall, patients may have cartilage recovery and good midterm functional outcomes.
  - Osteonecrosis is a difficult and often debilitating complication associated with SCFE and its treatment. It involves the death and possible collapse of the epiphysis because of disruption of its blood supply. Patients present with groin, thigh, or knee pain and limited hip motion.
  - Risk factors for osteonecrosis are unstable SCFE, pins in the posterosuperior quadrant of the epiphysis, an increased number of pins, and severe displacement. A stable slip has a nearly 0% risk of osteonecrosis, but an unstable slip has a 50% risk of osteonecrosis.
  - Treatment involves removal of prominent hardware if the physis has closed, limited weight bearing until healing, symptomatic management, and later reconstructive procedures.
  - Further slippage after in situ fixation occurs most frequently with improper screw placement outside of the desired middle third of the epiphysis and insufficient thread purchase into the epiphysis.

REFERENCES

FIG 2 • Osteonecrosis and collapse of the femoral head in a severe case of slipped capital femoral epiphysis. The in situ fixation had become prominent and has been removed. (Copyright Richard S. Davidson, MD.)
DEFINITION
- Pistol-grip deformity after slipped capital femoral epiphysis (SCFE) can cause anterior impingement leading to pain, cartilage and labral damage, and eventual osteoarthritis.1–3,8
- Realignment of the proximal femur, as well as restoration of the anterior head–neck offset, has been shown to improve hip scores.6
- This technique can be used to correct anterior impingement after a SCFE that has healed with residual posterior displacement.
- The first part of the procedure is a surgical hip dislocation with femoral head–neck osteoplasty.
- If additional deformity correction is needed, the flexion intertrochanteric osteotomy is performed.

PATHOGENESIS
- The true etiology of SCFE is unclear. However, because it occurs mainly in adolescent boys (80%), hormonal factors are thought to be involved.7
- Additionally, the orientation of the growth plate becomes more vertical in adolescents compared to the juvenile hip, leading to increased shear stress across the physis.
- The transition from juvenile to adolescent is a period of rapid weight gain, leading to the stereotypical body habitus in the SCFE patient.

NATURAL HISTORY
- Undetected SCFEs can lead to hip arthrosis. Murray suggested that up to 40% of hips with degenerative arthritis have a “tilt deformity” or other deformities that may be due to an undetected subclinical SCFE or other developmental problems.
- A review by Aronson found that 15% to 20% of patients with SCFE had painful osteoarthritis by age 50. Additionally, 11% of patients with end-stage osteoarthritis had a SCFE.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients will complain of insidious-onset groin or knee pain that may have previously been diagnosed as a sprain.
- They may walk with a limp, but typically they walk with an externally rotated foot progression angle, which may indicate chronic SCFE or femoral retroversion.
- Pain is elicited with hip flexion, adduction, and internal rotation stress (impingement test).
- The physical examination should include flexion and internal rotation range-of-motion tests. Normal, physiologic hip flexion needed for activities of daily living is at least 90 degrees.
- Patients with a chronic SCFE and anterior impingement will have less than 90 degrees of true hip flexion.
- Patients with impingement secondary to SCFE will have less internal rotation in flexion than extension, and may have a compensatory external rotation of the hip as it is flexed.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs include an anteroposterior (AP) and frog-leg lateral views of the pelvis or the involved hip (FIG 1A,B).
- Computed tomography (CT) scans with two- and three-dimensional reconstructions are helpful for preoperative planning (FIG 1C,D).

DIFFERENTIAL DIAGNOSIS
- Femoral or acetabular retroversion
- Hip dysplasia

NONOPERATIVE MANAGEMENT
- Nonoperative management includes cessation of aggravating activities and symptomatic treatment using nonsteroidal anti-inflammatories.
- Physical therapy to strengthen the hip musculature does not address the mechanical impingement associated with a SCFE.

SURGICAL MANAGEMENT
- A chronic slip may be pinned in situ to prevent continued slippage. Remodeling of the SCFE deformity has been described in long-term follow-up studies.
Corrective osteotomies have been described through the femoral neck at the growth plate (cuneiform), at the base of the femoral neck, or subtrochanteric.

Preoperative Planning

The anterior head–shaft angle is measured on the AP pelvis radiograph on both the affected and normal sides. The difference is the amount of varus deformity on the slip side that can be addressed with a valgus-producing intertrochanteric osteotomy (FIG 2A).

The lateral head–shaft angle is measured on the frog-leg lateral view in a manner similar to that used on the AP view. The difference is the amount of posterior deformity present that is corrected with a flexion-producing intertrochanteric osteotomy (FIG 2B).

Positioning

Because the first part of the procedure is done through a surgical hip dislocation, the patient is placed in the full lateral position secured on a pegboard, as shown in Chapter PE-76, Figure 3. A flat-top cushion placed beneath the operative side is helpful to stabilize the leg during the approach.

A hip drape with a sterile side bag is used, which will capture the leg during the dislocation maneuver.

Approach

The incision from the surgical hip dislocation is extended slightly distal, along the lateral aspect of the thigh, in line with the femoral shaft.

The lateral approach to the proximal third of the femur is required for the intertrochanteric osteotomy.

The longitudinal incision from the surgical hip dislocation can be extended distally, in line with the lateral shaft of the femur (TECH FIG 1A).

The vastus lateralis, supplied by the femoral nerve, is reflected anteriorly from the vastus ridge distally.

Several perforating vessels from the profunda femoris artery to the vastus lateralis should be identified and coagulated before they are avulsed by blunt dissection (TECH FIG 1B).

The anterolateral aspect of the femoral shaft is then exposed subperiosteally, and the lesser trochanter is identified.
Chapter 80  FLEXION INTERTROCHANTERIC OSTEOTOMY FOR SEVERE SCFE

**TECH FIG 1**  •  **A.** The proposed incision after the patient is prepared and draped. **B.** Approach to the intertrochanteric region of the femur. The vastus lateralis is reflected anteriorly from its origin at the vastus ridge.

**PLANNING THE OSTEOTOMY**

- A 2-0 Kirschner wire is placed just above the level of the lesser trochanter, beginning in the lateral cortex of the proximal femur. This is placed parallel to the floor in the axial plane and perpendicular to the shaft of the femur in the coronal plane. This is the reference for the level of the osteotomy.

- A second Kirschner wire is placed 3 cm proximal to the first. This is placed parallel to the first guidewire in the axial plane. In the coronal plane, the Kirschner wire is placed with an appropriate amount of valgus, determined from the anterior head-shaft angle difference on preoperative radiographs. This will act as the guidewire for the seating chisel for the blade plate.

**CREATING THE SLOT FOR THE BLADE PLATE**

- The seating chisel is directed parallel to the most proximal guide pin with the appropriate amount of flexion, as determined on the frog-leg lateral head-shaft angle difference.

- A slot for the blade plate should now be made in the trochanteric fragment to allow for anatomic fixation of the trochanter after the osteotomy.

- The blade plate chisel is placed into the proximal fragment after preparation of the trochanteric flip fragment and before cutting the intertrochanteric osteotomy (**TECH FIG 2**).

**OSTEOTOMY**

- Before osteotomy, a rotational reference mark is made at the level of the osteotomy on both the proximal and distal fragments.

- Using an oscillating saw, the proximal femur is cut using the Kirschner wire as a guide. The cut should be made perpendicular to the shaft of the femur.
POSTOPERATIVE CARE

- The hip is held flexed and in neutral rotation by placing two pillows under the leg and one under the greater trochanter.
- The patient is placed in a continuous passive motion machine for 6 hours a day, set from 30 to 80 degrees of flexion.
- Prophylaxis for deep venous thrombosis is individualized; however, all patients should be started on mechanical compression devices immediately.
- After the epidural is removed, out-of-bed ambulation is permitted with one-sixth body weight partial weight bearing.
- Range-of-motion exercises are started, but care is taken to protect the greater trochanter osteotomy by limiting adduction to midline, and avoiding resisted abduction exercises for 6 weeks.
- AP and true lateral hip radiographs are obtained to evaluate healing of the osteotomy (FIG 3A,B).
- Prominent hardware may be removed after 6 months if radiographic evidence of a healed osteotomy is seen (FIG 3C,D).

OUTCOMES

- In Southwick’s original article, where he treated the deformity with a proximal femoral osteotomy without surgical hip dislocation, out of 28 hips (26 patients) with at least 5 years of follow-up, 21 were rated as excellent, 5 as good, and 2 as fair.
In patients who had both osteoplasty and an intertrochanteric osteotomy, Western Ontario and McMaster Universities (WOMAC) pain and function scores improved in four of six patients. In patients who had both osteoplasty and an intertrochanteric osteotomy, Western Ontario and McMaster Universities (WOMAC) pain and function scores improved in four of six patients.

Internal rotation in flexion improved from −20 to +10 degrees.

There were no cases of avascular necrosis in a series of 19 patients treated with osteoplasty or osteoplasty with intertrochanteric osteotomy.

### COMPLICATIONS

- Avascular necrosis of the femoral head can occur if care is not taken to follow the technique and to preserve the retinacular vessels.
- Nonunion of the greater trochanteric osteotomy or the intertrochanteric osteotomy
- Sciatic or femoral nerve neurapraxia
- Heterotopic ossification

### REFERENCES

DEFINITION

- Triple arthrodesis involves fusion of the talocalcaneal, calcaneocuboid, and talonavicular joints. The procedure is most commonly indicated for salvage in severe, rigid deformities of the hindfoot that are unresponsive to less invasive methods of treatment.
- This procedure is typically considered in adolescents but has been reported in children as young as 8 years of age.

ANATOMY

- Joints of the hindfoot include the ankle, subtalar, talonavicular, and calcaneocuboid.
- Motions at the ankle joint include plantarflexion and dorsiflexion. As the ankle joint is oriented along the transmalleolar axis, dorsiflexion is associated with outward deviation of the foot, while plantarflexion is associated with inward deviation.
- The subtalar joint consists of an anterior, a middle, and a posterior facet. The anterior and middle facets are confluent in a subset of patients. While there is considerable variation, this joint is oriented 23 degrees medially in the transverse plane and 42 degrees dorsally in the sagittal plane. The subtalar joint thus functions as a hinge along an inclined axis and serves as the linkage between the ankle and the distal articulations of the foot. During the gait cycle, the subtalar joint is everted at heel strike and then inverts progressively until the time of push-off.
- The talonavicular and calcaneocuboid joints are known as the transverse tarsal joints. When the calcaneus is everted, these joints become parallel, and there is greater flexibility at the articulation. This aids in shock absorption during initial contact and early stance phase. In contrast, the transverse tarsal joints become nonparallel (more rigid) when the calcaneus is inverted. Functionally, the calcaneus becomes inverted during late stance phase, which locks the transverse tarsal joints and provides a rigid lever for push-off.
- From a functional standpoint, the muscles crossing the ankle and subtalar joints may be classified based on their location with respect to each joint axis. There is plantarflexion (gastrocnemius and soleus, tibialis posterior, flexor digitorum longus, flexor hallucis longus) and dorsiflexion (tibialis anterior, extensor digitorum longus, extensor hallucis longus) at the ankle. The movements of inversion (tibialis anterior and posterior, flexor digitorum longus, flexor hallucis longus) and eversion (peroneus longus, brevis, tertiarius, extensor digitorum longus, extensor hallucis longus) occur across the subtalar axis.

PATHOGENESIS

- Foot deformities in children most frequently result from a congenital condition (clubfoot, vertical talus, tarsal coalition) or occur in association with a variety of neuromuscular diseases. In the latter, the cause involves muscle weakness or imbalance, and examples include either flaccid or spastic neuromuscular dys-function (cerebral palsy, poliomyelitis, myelomeningocele, hereditary motor and sensory neuropathies, other).
- The most common deformities are equinovarus, equinovarus, and cavovarus. Calcaneovalgus, calcaneovalgus, calcaneovarus, and equinocavus may also be seen. This spectrum of deformities may result from soft tissue contractures, from bony malalignment, or from both.
- While some deformities have a structural component at birth, most develop gradually, are initially flexible, and become fixed or rigid only over time. While a loss of passive motion may result from contracture of the soft tissue elements, progressive adaptive changes in the osteocartilaginous structures subsequently result in fixed bony malalignment.
- The equinovarus deformity is present at birth in a congenital clubfoot, or may result from spastic muscle imbalance in patients with cerebral palsy (most often spastic hemiplegia) or flaccid muscle imbalance (poliomyelitis). While the cause of congenital clubfoot remains debated, and is most likely multifactorial, the pathogenesis in neuromuscular diseases involves muscle imbalance (strong inversion–plantarflexion and weak eversion–dorsiflexion).
- An equinovarus deformity is most common in patients with a congenital vertical talus or cerebral palsy (most commonly spastic diplegia). A valgus deformity of the hindfoot is common in patients with a tarsal coalition.
- The cavovarus foot is most common in the hereditary motor and sensory neuropathies (Charcot-Marie-Tooth disease) and results from muscle imbalance. Weakness of the tibialis anterior (relative to the peroneus longus) is associated with plantarflexion of the first ray (forefoot valgus), a deformity that is initially flexible.
  - Over time, a contracture of the plantar fascia and neighboring intrinsic muscle groups develops. To compensate for forefoot valgus, the hindfoot aligns in varus during stance phase.
  - Both the forefoot valgus and the hindfoot varus eventually become rigid. The hindfoot also appears to be in equinus because of plantarflexion of the midfoot on the hindfoot. A common mistake is to assume that the equinus occurs at the ankle and to perform an Achilles tendon lengthening.

NATURAL HISTORY

- The natural history depends on the underlying disease process.
- Deformities associated with the neuromuscular diseases will usually progress (and become rigid) over time and will have a significant chance of recurrence despite treatment owing to the underlying disease process.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients present with an abnormality or change in appearance of the foot, gait disturbance, pain in the region of the hindfoot, difficulties with shoe wear, or more than one of these. While the deformities treated by triple arthrodesis may be diagnosed from birth to adolescence and have
often been treated previously, we will focus on the older child or adolescent.

- The history focuses on the presence of symptoms, including functional limitations, cosmetic concerns, and shoe wear, the family history (similar deformities, neuromuscular diseases), and previous treatment.
- A detailed history is especially important in children of walking age, as a foot deformity may be the first clue to the presence of an underlying neuromuscular problem. While unilateral foot deformities may be seen with tethering of the spinal cord (or other problems such as a spinal cord tumor), bilateral deformities may be the initial finding in patients with a hereditary motor and sensory neuropathy.
- The location and character of pain should be determined, in addition to the activities that produce discomfort.
- A comprehensive physical examination is required. The spine should be examined to rule out any deformity or evidence of an underlying dysraphic condition, and a careful neurologic examination should be performed. The extremities are evaluated for alignment, limb lengths, and range of motion. Observational gait analysis should be performed. The shoes should be inspected for patterns of wear, which indicate weight distribution during stance phase.
- The physical examination of the foot and ankle focuses on the skin (presence and location of callosities, points of tenderness), the overall appearance in both the weight-bearing and non-weight-bearing positions (relationship between the forefoot and hindfoot), the range of motion of the hindfoot joints, the relationship between the forefoot and the hindfoot, and the neuromuscular assessment.
- Tests to perform during the physical examination include:
  - Range of motion at the ankle joint (plantarflexion and dorsiflexion) to diagnose and determine the magnitude of equinus contracture
  - Range of motion at the subtalar joint (inversion and eversion), which quantifies motion at the subtalar joint. Generally, the amount of inversion is twice the amount of eversion. The total range is 20 to 60 degrees.
  - Range of motion at the transverse tarsal joints
  - Relationship between forefoot and hindfoot alignment, which identifies any coexisting deformity of the forefoot, either varus (the lateral aspect of the forefoot axis is more plantarflexed than the medial aspect) or valgus (medial aspect of the forefoot axis is more plantarflexed than the lateral forefoot axis)
  - Coleman block test, which determines if hindfoot varus is flexible or rigid
  - Manual muscle testing, which assesses relative strengths of motor units across the ankle and subtalar joints. This helps to diagnose muscle imbalance and to plan tendon transfers if appropriate.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Imaging studies complement the history and physical examination, and plain radiographs in a weight-bearing position are required in all cases. In addition to a standing anteroposterior (AP) and lateral radiograph of the foot, a standing AP of the ankle should be obtained to determine whether the deformity is in the ankle joint, the subtalar joint, or both locations. Other imaging modalities such as a CT scan or MRI may be required in selected cases.
- Plain radiographs are used to evaluate bone and joint morphology, and measuring the angular relationships between the tarsal bones (or segments of the foot) helps to further define both the location and the magnitude of deformities.
- On the standing AP radiograph, measurements include the talocalcaneal (Kite) angle (10 to 36 degrees) and the talus–first metatarsal angle (range –10 to +30 degrees). For the AP talocalcaneal angle, values less than 20 degrees suggest hindfoot varus, while an angle greater than 40 to 50 degrees suggests hindfoot valgus. For the talo–first metatarsal angle, values less than –10 degrees indicate forefoot varus and values greater than +30 degrees indicate forefoot valgus.
- On the standing lateral radiograph of the foot, measurements include the lateral talocalcaneal angle, the tibiotalocalcaneal angle, and the talus–first metatarsal angle.
- For the lateral talocalcaneal angle (range 25 to 55 degrees), values greater than 55 degrees indicate hindfoot valgus or calcaneus, while values less than 25 to 30 degrees indicate hindfoot varus or equinus deformities.
- For the tibiotalocalcaneal angle (55 to 95 degrees), values greater than 95 degrees suggest equinus, while those below 55 degrees are suggestive of calcaneus.
- For the talus–first metatarsal angle, or Meara angle (0 to 20 degrees), values greater than 20 degrees indicate midfoot equinus (cavus), while values less than 0 degrees indicate midfoot dorsiflexion (midfoot break).
- The angle of the calcaneus relative to the horizontal axis (calcaneal pitch) is increased with calcaneus or calcaneo-cavus, or with cavovarus deformities.

**DIFFERENTIAL DIAGNOSIS**

- Equinovarus: congenital clubfoot, poliomyelitis or other flaccid weakness or paralysis, spastic hemiplegia, other
- Equinovarus: congenital vertical talus, spastic diplegia or quadriplegia, tarsal coalition, flexible flatfoot with tight Achilles tendon, other
- Cavovarus: hereditary motor and sensory neuropathies, poliomyelitis or other flaccid weakness or paralysis, myelomeningocele, other

**NONOPERATIVE MANAGEMENT**

- The goals of nonoperative treatment are to achieve correction, to maintain correction, and to prevent recurrence of the deformity. The specific treatments are based on the underlying disease process, and options include physical therapy, injection of botulinum A toxin, serial casting, and orthoses.
- Physical therapy is directed toward improving range of motion and improving strength.
- Serial casting may help to improve range of motion.
- Botulinum toxin injections result in a reversible chemical denervation of the muscle group (for 3 to 8 months) and have been used most frequently in patients with cerebral palsy to decrease spasticity and reduce dynamic muscle imbalance. Such treatment may prevent or delay the need for surgical intervention in patients with spastic equinovarus or equinovalgus.
- Orthoses may be used to maintain alignment during ambulation, or as a nighttime splint to prevent the development of...
contractures. The deformity should ideally be passively correctable. Foot orthoses such as the UCBL may help to control varus–valgus alignment of the hindfoot during ambulation. An ankle–foot orthosis improves prepositioning of the foot during swing phase, provides stability during stance phase, and can be used as a night splint.

**SURGICAL MANAGEMENT**

- Surgical treatment is offered when nonoperative measures have failed to alleviate the symptoms. Triple arthrodesis is a salvage procedure or “last resort” for rigid deformities in older patients, many of whom have been previously treated by both nonoperative and operative strategies.
- The procedure is often performed for the correction of rigid deformities, which typically requires removal of bony wedges. As such, careful preoperative planning is required to determine the appropriate size and location of these wedges. Triple arthrodesis shortens the foot, which may be cosmetically objectionable.
- Arthrodesis transfers additional stresses to neighboring joints, which may result in degenerative changes and pain. While there are reports of the procedure being successful in children as young as 8 years, it has been suggested that surgery should be delayed until the foot has reached adult proportions. One recent study concluded that growth rates were no different in those children treated before or after 11 years of age.
- The deformity should be of sufficient severity that soft tissue releases and osteotomies would be unlikely to achieve correction, or when painful degenerative changes are observed in the joints of the hindfoot. The most common indications are recurrent or neglected (most commonly seen in developing nations) clubfoot, cavovarus associated with Charcot-Marie-Tooth disease, and severe equinovalgus deformities in patients with spastic diplegia.
- The goal of surgery is to achieve a plantigrade foot by restoring the anatomic relationships between the affected bones or regions of the foot, and to relieve pain.
- Additional procedures may be required. An equinus deformity of the ankle will require a lengthening of the tendo Achilles at the time of triple arthrodesis. The treatment of a coexisting forefoot may require soft tissue release, tendon transfer, or osteotomy, or some combination of these (usually as another stage). In patients with neuromuscular diseases, lengthening or transfer of tendons crossing the hindfoot may be required to restore muscle balance and prevent further deformity. Recurrence of deformity may occur when coexisting muscle imbalance has not been treated.³,15
- A hindfoot arthrodesis should be avoided in patients with insensate feet (myelomeningocele, other).
- While triple arthrodesis is routinely performed without fixation (or with minimal fixation such as Kirschner wires or staples) in many parts of the world, fixation with staples or screws reduces the chances of correction loss and pseudarthrosis.
- Biomechanical studies have demonstrated no significant difference in stability when comparing fixation with staples versus cannulated screws.⁸,⁹

**Preoperative Planning**

- Weight-bearing radiographs are used to evaluate the relationships between the tarsal bones, to identify any morphologic abnormalities or degenerative changes, and to identify the location of the deformity. These radiographs help to plan the location of wedge resections.

**Positioning**

- The patient is placed supine, and a bump may be placed under the ipsilateral hip.
- A tourniquet is applied around the thigh.

**Approach**

- Several skin incisions have been described for triple arthrodesis, and the specific choice may depend on the type of deformity and the previous experience of the surgeon. These include the single lateral or anterolateral approach, the medial approach, and a combined lateral and medial approach.
- The lateral approach (Ollier) is used most commonly and allows excellent visualization of all three joints (FIG 1).
- A medial approach may be useful for calcaneovalgus foot, and the Lambrinudi procedure is considered for severe equinus deformity. The articular surfaces of the talonavicular, calcaneocuboid, and subtalar joints are removed to achieve arthrodesis.
- Modifications of this basic technique are based on the underlying deformity and involve bony wedge resections to correct specific components of the deformity.

---

FIG 1 • The lateral approach is used most frequently. **A.** The skin incision extends from distal to the fibular malleolus across the sinus tarsi. **B.** All three joints can be visualized after dissection of the subcutaneous tissues, elevation of the extensor digitorum brevis off the anterior process of the calcaneus, and opening of the joint capsules. **C.** Placement of a laminar spreader may facilitate visualization of the posterior facet of the subtalar joint.
Chapter 81  TRIPLE ARTHRODESIS

PENNY’S MODIFIED LAMBRINUDI TRIPLE ARTHRODESIS

- There are several unique features associated with the neglected clubfoot in adolescents that require special attention when performing a triple arthrodesis.5
  - A lengthening of the tendo Achilles is required and is performed as the first step.
  - The main components are hindfoot equinus and varus, midfoot cavus, and forefoot adduction.
  - In contrast to other hindfoot deformities, there is always significant obliquity of the calcaneocuboid joint, which requires a specially oriented lateral wedge excision of the calcaneocuboid joint.
  - The foot is typically severely plantarflexed, and this component of the deformity comes from both the hindfoot equinus and the midfoot cavus.
  - An aggressive resection of the talar head is commonly required to correct the midfoot cavus and bring the forepart of the foot to a plantigrade position.

Incision and Dissection

- The skin incision is started 1 cm distal to the tip of the fibula. It is curved dorsolaterally and extends to the lateral border of the talonavicular joint.
- After spreading the subcutaneous tissues, the extensor tendons are retracted medially and the peroneal tendons are mobilized and protected. The sural nerve is also identified and protected (TECH FIG 2).
- The extensor digitorum brevis is elevated off its origin and reflected distally, exposing the sinus tarsi, the calcaneocuboid joint, and the lateral aspect of the talonavicular joint.
- Soft tissues are cleared from the sinus tarsi, which promotes visualization of the facets of the subtalar joint. The anterior and middle facets will be confluent in a subset of cases.

Arthrodesis

- The first step of the procedure involves removing a lateral wedge (calcaneocuboid resection) to shorten the lateral border of the foot (TECH FIG 3A). One unique feature of the neglected clubfoot is the obliquity at the calcaneocuboid joint.
  - An osteotome or oscillating saw is used to make a transverse cut perpendicular to the long axis of the lower leg.
  - The second cut removes the joint surface of the cuboid and should be conservative (several millimeters). Most of this wedge resection comes from the calcaneus.
- The second step involves removing an anteriorly based wedge from the anterior process of the calcaneus to correct equinus of the forepart of the foot (TECH FIG 3B).
- The third step involves resecting a portion of the head and neck of the talus (TECH FIG 3C).
  - The cut begins at the dorsal articular margin of the talus and extends in a proximal and plantar direction through the posterior subtalar joint.

TECH FIG 1 • The bony segments are removed to correct the neglected clubfoot. Conservative resection is shown in blue and aggressive resection in red.

TECH FIG 2 • Lateral exposure. (From Penny JN. The neglected clubfoot. Tech Orthop 2005;7:19–24.)
This cut is oriented perpendicular to the long axis of the tibia. This essentially removes the entire talus head and a portion of the talus neck.

The fourth step involves a conservative resection of the articular surface of navicular, as well as removal of the tuberosity of the navicular.

A notch is made in the inferior articular surface of the navicular to accept the anterior portion of the talus.

With the surfaces of the talus and calcaneus apposed, the anterior end of the talus is pushed into the notch under the navicular while abducting the forefoot (TECH FIG 3D).

Fixation is usually achieved with Kirschner wires, staples, or screws (TECH FIG 3E).

The heel varus usually corrects spontaneously.

---

The incision begins 1 cm distal to the tip of the fibula; it curves dorsolaterally and extends to the lateral border of the talonavicular joint.

The extensor tendons are retracted medially, while the peroneal tendons are mobilized and protected. The extensor digitorum brevis is reflected distally, exposing the sinus tarsi, the calcaneocuboid joint, and the lateral aspect of the talonavicular joint.

The sinus tarsi is cleared of soft tissue to expose the anterior, middle, and posterior facets of the subtalar joints.

Sequential osteotomies are made with a broad osteotome or power saw (TECH FIG 4A).
The first osteotomy is made along the inferior part of the talus perpendicular to the long axis of the tibia in both planes. The second osteotomy is made along the superior part of the calcaneus parallel to the sole of the foot in both the longitudinal and transverse planes. The third cut is made at the distal end of the calcaneus at a right angle to the long axis of the calcaneus. The final cut is made along the proximal end of the cuboid at a right angle to the longitudinal axis of the forefoot.

A groove is fashioned in the inferior proximal part of the navicular to accept the anterior end of the talus. The osteotomized surfaces are approximated (TECH FIG 4B) and held with staples. The extensor digitorum is lightly sutured back into place, and the subcutaneous tissue and skin edges are reapproximated.

A 2-cm longitudinal incision is made over the peroneal tendons 10 cm above the level of the ankle joint, and both tendons are delivered using a mosquito clamp and divided sharply. An 8-cm medial longitudinal incision extends from the undersurface of the posterior medial malleolus across the talonavicular joint. The talonavicular joint is exposed, and the tibialis posterior tendon is released from its insertion. The talonavicular capsule is released. Flexor digitorum longus tendon, flexor hallucis tendon, and neurovascular bundle are protected by a retractor.

The talocalcaneal interosseous ligament is divided, and the anterior, middle, and posterior facets of the subtalar joint are visualized. The subtalar and talonavicular joint surfaces are denuded and prepared. The calcaneocuboid joint capsule and bifurcate ligaments are released sharply, and a lamina spreader is inserted to facilitate removal of the joint surfaces. Fixation of the subtalar joint is achieved with a single 6.5-mm cannulated screw from the posterior calcaneus into the talar body. The talonavicular and calcaneocuboid joints are realigned and stabilized with 5-mm cannulated screws.

A lateral approach is employed, as outlined above. Wedges to be removed are shown in TECHNIQUES FIGURE 5A. The articular cartilage of the subtalar and calcaneocuboid joints is denuded. The talar neck is osteotomized from inferior to superior, forming a beak superiorly. The soft tissue structures on the superior aspect of the talus anterior to the ankle are left undisturbed.

The dorsal cortex of the navicular is excised. The forefoot is displaced plantarward and the navicular is locked beneath the remaining part of the talar head and neck. Stability can be maintained while plaster is applied by slight upward pressure under the forefoot (TECH FIG 5B). A staple may be used for fixation.

TECH FIG 5 • Beak arthrodesis technique. A. Wedges to be removed. B. Final alignment after correction.
POSTOPERATIVE CARE
- The limb is typically immobilized in a short- or long-leg cast for at least 6 weeks, and weight bearing is permitted after 6 weeks.
- An ankle-foot orthosis may be required in patients with a neuromuscular diagnosis.

OUTCOMES
- Most studies have involved mixed populations (children and adults) with a variety of diagnoses at early to midrange follow-up, using variable criteria (objective and subjective) to assess outcome.
- Overall, successful results have been reported in most patients, with patient satisfaction in the range of 50% to 95%. Rates of union are 89% to 95%. In general, poor outcomes have been associated with residual deformity or pseudarthrosis.
- Outcomes seem to be similar when comparing children and adults. The results vary somewhat based on the underlying diagnosis, and they seem to deteriorate with longer-term follow-up.
- Most patients have difficulty walking on uneven surfaces. Instrumented motion analysis studies by Beischer et al17 and Wu et al17 revealed an increase in ipsilateral knee flexion during stance phase (including push-off) and a loss of ankle plantarflexion during push-off. Power generation at the ankle is decreased up to 45%.
- Degenerative changes are common in the surrounding joints at long-term follow-up but do not imply the presence of pain or a deterioration in results. Chronic pain is seen in a subset of cases.
- In cerebral palsy, Ireland et al6 found excellent results in all patients at 4.5 years of follow-up. Tenuta et al14 found that 80% of patients were satisfied at 18 years of follow-up, although 25% had occasional pain and 14% had persistent pain. Lack of satisfaction was correlated with residual deformity or pain.
- The results in patients with cavovarus feet (Charcot-Marie-Tooth) are less predictable.
- At 12 years of follow-up, Wukich and Bower18 observed excellent or good results in 88%, with 15% pseudarthrosis and degenerative changes in 64%.
- At 21 years of follow-up, Wetmore et al15 found excellent or good results in only 24%, with recurrence in nearly 50% because of progressive weakness or muscle imbalance. Twenty percent required conversion to a pantalar arthrodesis for ankle pain associated with degenerative changes.
- With flaccid neuromuscular imbalance (poliomyelitis), the results have been adequate in most patients, provided that adequate muscle balance has been achieved in addition to the arthrodesis. Grego et al13 found recurrence in 20% of patients, mostly due to persistent muscle imbalance.

INLAY GRAFTING METHOD FOR VALGUS DEFORMITY
(MODIFIED TECHNIQUE OF WILLIAMS AND MENELAUS)
- The original technique by Williams and Menelaus16 involves placing an inlay graft from the tibia. El-Batouty et al4 modified this to obviate the need for a medially based closing wedge osteotomy for valgus deformity of the hindfoot.
- An anterolateral exposure is used, as described previously.
- The joint surfaces are removed, and the hindfoot is realigned and stabilized with two Kirschner wires.
- An inlay graft is taken from the tibia and placed into a rectangular trough created across the talonavicular, calcaneocuboid, and anterior subtalar joints (TECH FIG 6).
- The posterior subtalar joint is then denuded and local bone graft is placed.
- A cast is applied, and the Kirschner wires are removed.

TECH FIG 6 • Modified Williams and Menelaus’s inlay grafting technique.
COMPLICATIONS

- Injury to neurovascular or tendinous structures. The medial neurovascular bundle and flexor hallucis longus tendon must be protected during resection of the posterior facet of the subtalar joint.
- Wound infection
- Wound breakdown or skin necrosis
- Pseudarthrosis of one or more joints, most commonly the talonavicular
- Residual deformity
- Recurrent deformity may be observed in patients with progressive neuromuscular disease (Charcot-Marie-Tooth) or persistent muscle imbalance (poliomyelitis, cerebral palsy).
- Degenerative changes are commonly observed at long-term follow-up (longest study is 44 years) and result from increased stress transmission to the neighboring joints. These changes may be observed in the midfoot (54% to 99%\(^1,11,18\)) or the ankle joint (24% to 100%\(^11,14,18\)).
- Pain from persistent malalignment, degenerative changes, or avascular necrosis of the talus
- Difficulties with shoe wear
- Need for orthotic support or an assistive device for ambulation

REFERENCES

DEFINITION
- Flatfoot is the term used to describe a weight-bearing foot shape in which the hindfoot is in valgus alignment, the midfoot sags in a plantar direction with reversal of the longitudinal arch, the forefoot is supinated in relation to the hindfoot, and the foot points in an externally rotated direction from the knee.
- There is no agreement on strict clinical or radiographic criteria for defining a flatfoot. Therefore, the point beyond which a foot with a low-normal arch becomes defined as a flatfoot is unknown.
- There are three recognized types of flatfoot: flexible (hypermobile) flatfoot, flexible (hypermobile) flatfoot with a short Achilles tendon, and rigid flatfoot.

ANATOMY
- A flatfoot combines valgus deformity of the hindfoot with supination deformity of the forefoot to create a low or absent longitudinal arch (FIG 1). These are rotationally opposite deformities.
- Valgus deformity of the hindfoot, which can also be described as pronation, is one component of eversion of the subtalar joint.
- The other components are external rotation and dorsiflexion of the acetabulum pedis in relation to the plantarflexed talus.
- Acetabulum pedis is a term, coined over 200 years ago by Scarpa, used to describe and compare the subtalar joint with the hip joint, because of certain similarities. It is a cup-like structure consisting of the navicular, spring ligament, and anterior end of the calcaneus that rotates around the talus following the axis of the subtalar joint.
- The axis of the subtalar joint is not in any of the standard planes of motion of the body. In the transverse plane, the subtalar axis deviates about 23 degrees medial to the long axis of the foot. In the horizontal plane, the axis deviates about 41 degrees dorsal from horizontal. The summation of the angles creates an axis for the subtalar joint that produces downward and inward motion during inversion, and upward and outward motion during eversion.
- Eversion of the acetabulum pedis results in loss of support and plantarflexion of the talus. Although the calcaneus dorsiflexes “upward” in relation to the talus, it becomes plantarflexed in relation to the weight-bearing tibia. The navicular also dorsiflexes “upward” at the talonavicular joint as the focal point for the midfoot sag. “Outward” motion of the acetabulum pedis creates the external rotation of the foot in relation to the talus and tibia that is manifest as a positive thigh-foot angle and an out-toeing gait. Convexity of the plantar-medial border of the foot is also a manifestation of “outward” motion of the acetabulum pedis, reflecting the dorsolateral subluxation of the navicular on the head of the talus.
- The forefoot, in a flatfoot, is supinated in relation to the pronated hindfoot. Were it not, forefoot weight bearing would occur solely on the first metatarsal. Finally, these altered relationships create a real, or apparent, shortening of the lateral column (or border) of the foot relative to the medial column.
- The shapes of the bones and the laxity of the ligaments of the foot determine the height of the longitudinal arch. The muscles maintain balance, accommodate the foot to uneven terrain, protect the ligaments from unusual stresses, and propel the body forward. The intrinsic muscles are the principal stabilizers of the foot during propulsion. Greater intrinsic
muscle activity is required to stabilize the transverse tarsal and subtalar joints in a flatfooted individual than in an individual with an average height arch.

**PATHOGENESIS**

- Based on clinical and radiographic studies, flatfoot is ubiquitous in infants and children and is seen in over 20% of adults. The arch increases in height in most children through normal growth and development during the first decade of life. The arch decreases in height in most of those older children and adolescents who have a rigid flatfoot, a condition affecting about 2%–5% of the population that is most often associated with a tarsal coalition.
- Flexibility (hypermobility) in a flexible flatfoot refers to the motion in the subtalar joint. There is full excursion of the Achilles tendon in this class of flatfoot. It is the normal foot shape seen in almost all babies and accounts for about two thirds of the 23% of flatfooted adults. It is the normal contour of a strong and stable foot, not the cause of disability.
- A flexible flatfoot with a short Achilles tendon has the same flexibility in the subtalar joint as a flexible flatfoot, but has limited ankle dorsiflexion owing to contracture of the Achilles tendon. This entity accounts for about one fourth of the 23% of flatfooted adults and often causes pain with callus formation under the head of the talus. The age or point at which the Achilles tendon contracture develops is unknown.
- Rigidity in a rigid flatfoot refers to the restriction of motion in the subtalar joint. This type of flatfoot accounts for about 9% of the 23% of flatfooted adults. It is usually associated with a tarsal coalition and is, therefore, developmental rather than congenital, like the flexible flatfoot. It causes pain in about 25% of cases.
- A contracted Achilles tendon prevents normal dorsiflexion of the talus in the ankle joint during the late midstance phase of the gait cycle. The dorsiflexion stress is shifted to the subtalar joint complex where, as a feature of eversion, the acetabulum pedis dorsiflexes in relation to the talus and also in relation to the tibia. The talus remains rigidly plantarflexed. The soft tissues under the head of the talus are subjected to excessive direct axial loading and shear stresses.
  - These stresses create callus formation and pain at that site.
  - Pain may also be experienced in the sinus tarsi region because of impingement of the beak of the calcaneus with the lateral process of the talus at the extreme range of eversion.

**NATURAL HISTORY**

- Flatfoot is a poorly defined foot shape found in most children and over 20% of adults. For most, it is an anatomic variation from average that does not cause pain or other disability.
- The longitudinal arch develops spontaneously in most children during the first decade of life. Flexible flatfoot with a short Achilles tendon often causes pain with callus formation under the head of the talus or pain in the sinus tarsi area.
- The age or point at which the Achilles tendon contracture develops is unknown.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Children with flexible flatfoot are rarely symptomatic, although they may experience nonspecific leg or foot aches after strenuous activities or at the end of the day. Older children and adolescents with flexible flatfoot with a short Achilles tendon will often experience pain, tenderness, and callus formation under the head of the plantarflexed talus in the midfoot or in the sinus tarsi area or at both sites. About 25% of children and adolescents with a tarsal coalition report activity-related pain that may be located in the sinus tarsi area, along the medial hindfoot, or under the head of the talus.
- Commonly, parents seek consultation for their child with a painless flatfoot because of concerns regarding the appearance of the foot, the child’s uneven shoe wear, or the concern about the potential for future disability. Such concerns about future disability are based on unsubstantiated claims by generations of health care professionals that flatfoot is a deformity that requires treatment to prevent pain and disability.
- Examination of the child’s foot should begin with a screening evaluation of the entire musculoskeletal system. The general examination is aimed at assessing ligament laxity, torsional and angular variations of the lower extremities, and the walking pattern. Their interrelationships are important to keep in mind during evaluation of the foot because all of these features change as the child grows.
- Assessment of the foot begins with the recognition that a flatfoot is not a deformity. It is a combination of deformities that includes a valgus deformity of the hindfoot and a supination deformity of the forefoot on the hindfoot. There is a lateral rotational deformity as well. The axis of the subtalar joint is in an oblique plane, such that eversion creates valgus, external rotation, and dorsiflexion of the so-called acetabulum pedis around the talus.
- The flexibility of the flatfoot pertains to the mobility of the subtalar joint. This can be assessed manually. With the hindfoot in your cupped hand and your other hand on the forefoot, the subtalar joint is inverted and everted around the oblique axis of motion of the joint (FIG 2). Ensure that the motion you appreciate is in the subtalar joint, and not false motion through Chopart’s joints.
- A flexible flatfoot has free and supple subtalar joint motion in the axis of the joint. A rigid flatfoot has restriction of

![FIG 2](image-url) Inversion and eversion of the subtalar joint is assessed by manually moving the acetabulum pedis back and forth along the axis of the subtalar joint. Forefoot supination can be appreciated when the hindfoot is inverted to neutral. While maintaining subtalar joint neutrality, the ankle is dorsiflexed with the knee first flexed and then extended to assess the excursion of the soleus and the gastrocnemius respectively. (From: Mosca VS. Flatfoot and skewfoot. In: Drennan J, ed. The Child’s Foot and Ankle. New York: Raven Press, 1992:355–376.)
motion. This can also be seen dynamically. The arch elevates and the hindfoot corrects from valgus to varus in a flexible flatfoot during toe standing (FIG 3) and with the Jack toe raise test. These two maneuvers take advantage of the windlass action of the plantar fascia to mobilize the subtalar joint into inversion and create a longitudinal arch.

- Supination of the forefoot is revealed when the hindfoot is passively inverted to neutral alignment see Fig 2.
- Functional motion of the ankle joint, as assessed by excursion of the Achilles tendon, is important yet difficult to evaluate accurately. A component of subtalar joint eversion is dorsiflexion of the calcaneus in relation to the talus. Therefore, the subtalar joint must be held inverted to the neutral position to isolate and assess the motion of the talus in the ankle.
- With the subtalar joint inverted to neutral, the knee is flexed to 90 degrees. The ankle is maximally dorsiflexed without allowing the subtalar joint to evert. The degree of dorsiflexion is measured as the angle between the lateral border of the foot and the anterior shaft of the tibia. The knee is then extended while maintaining subtalar neutral, even if it creates plantar flexion of the ankle. The degree of ankle dorsiflexion is once again measured.
- It is normal for the ankle to dorsiflex at least 10 degrees above neutral with the knee flexed, and even further with the knee flexed. The entire triceps surae (gastrocnemius and soleus) is contracted if the ankle does not dorsiflex at least 10 degrees above neutral with the knee flexed or extended. The gastrocnemius is selectively contracted if the ankle dorsiflexes at least 10 degrees above neutral with the knee flexed, but not when it is extended.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Radiographs of the flatfoot are not necessary for diagnosis. They may be indicated for the assessment of pain or decreased flexibility, and for surgical planning.
- Weight-bearing anteroposterior (AP), lateral, medial oblique, and axial (or Harris) views are appropriate for those indications (FIG 4).
- The lateral oblique view is helpful for the identification of an accessory navicular that could be the cause of a painful medial prominence in the midfoot that is not the head of the talus.
- Radiographs can define the static relationships between bones but cannot provide information on flexibility or function. They should not be used as an indication for treatment. A bone scan can help with the assessment of atypical pain in a flatfoot.
- A CT scan is useful for assessment of a rigid flatfoot, particularly when there is a high degree of suspicion for a subtalar tarsal coalition.
- An MRI may be necessary if these other imaging studies fail to reveal the etiology for atypical pain in a flatfoot.

**DIFFERENTIAL DIAGNOSIS**

- Flexible (hypermobility) flatfoot
- Flexible (hypermobility) flatfoot with short Achilles tendon

**FIG 3**• With toe standing, the heel vagus converts to varus and the longitudinal arch elevates in a flexible flatfoot. (From Mosca VS. Flatfoot and skewfoot. In: Drennan J, ed. The Child’s Foot and Ankle. New York: Raven Press, 1992:355-376.)

**FIG 4**• Standing radiographs of a flatfoot. A. AP image demonstrates the external rotation component of eversion or valgus of the subtalar joint. B. The lateral image reveals plantarflexion of the talus, sag at the talonavicular joint, and a low calcaneal pitch. (From the private collection of Vincent Mosca, MD.)
Chapter 82  CALCANEAL LENGTHENING OSTEOTOMY FOR THE TREATMENT OF HINDFOOT VALGUS DEFORMITY

NONOPERATIVE MANAGEMENT
- Flexible flatfoot is a normal foot shape and not the cause of pain or functional disability in most individuals. Therefore, treatment must be applied only to those who have symptoms. “Prophylactic” treatment, even if nonoperative, cannot be justified, based on the literature.
- Some children with flexible flatfoot have activity-related pain or pain at night in the leg or foot. The pain is usually nonlocalized and it is believed to represent an overuse syndrome. This is consistent with the finding that flatfooted individuals demonstrate greater intrinsic muscle activity than normal.
- Over-the-counter and molded shoe inserts have been shown to relieve or diminish symptoms and to increase the useful life of shoes without a simultaneous permanent increase in the height of the arch. There are few, if any, complications of orthotic treatment for flexible flatfoot.
- Children, adolescents, and adults with flexible flatfoot with a short Achilles tendon will often have pain with weight bearing and callous under the head of the plantarflexed talus.
  - The contracted Achilles tendon prevents normal dorsiflexion of the ankle joint during the midstance phase of gait. The dorsiflexion stress is shifted to the subtalar joint complex, which dorsiflexes as a component of eversion. The talus remains rigidly plantarflexed, thereby subjecting the soft tissues under the head of the talus to excessive direct axial loading and shear stress.
- Both firm and hard arch supports concentrate and exaggerate the pressures under the head of the talus in children with flexible flatfeet with short Achilles tendons, thereby exacerbating and enhancing pain. They are, therefore, contraindicated in this condition.
- An aggressive stretching program for the Achilles tendon, performed with the subtalar joint inverted, may relieve symptoms, but is challenging to carry out effectively.
- It is difficult to almost impossible to stretch a contracted Achilles tendon when it is associated with a flexible flatfoot. The subtalar joint must be inverted and held in neutral alignment for the Achilles to stretch. Otherwise, the apparent Achilles tendon stretch will merely create further eversion/varus stretch in the subtalar joint.

SURGICAL MANAGEMENT
- The calcaneal lengthening osteotomy is indicated for the flexible flatfoot with a short Achilles tendon when prolonged attempts at conservative management fail to relieve the pain under the head of the plantarflexed talus or in the sinus tarsi area.
- This procedure is not indicated to change the shape of a pain-free flexible flatfoot.
- Surgery should not be performed in young children with flexible flatfeet who have nonlocalized, activity-related aching foot pain or nighttime pain in the lower extremities.
- Surgery should not be carried out for incongruous signs or symptoms. In such situations, the flatfoot may be an incidental finding and not the cause of the symptoms.
- Finally, the calcaneal lengthening osteotomy is contraindicated in the iatrogenic flatfoot created by overcorrection of a clubfoot in which the talonavicular joint is well aligned and the thigh–foot angle is neutral despite the valgus alignment of the hindfoot.

Preoperative Planning
- Physical examination includes evaluation of the foot in weight bearing and non-weight bearing.
  - In weight bearing, the clinicians should note the valgus alignment of the hindfoot, the depression of the longitudinal arch, and the outward rotation of the foot in relation to the flexion–extension plane of the knee as referenced from the alignment with the patella.
  - Flexibility of the flatfoot is confirmed by observing the creation of the longitudinal arch and conversion of hindfoot varus to varus with toe standing see Fig 3.
- On the examining table, the clinician performs the Silfverskiöld test to determine if the equinus contracture is in the gastrocnemius alone or involves the entire triceps surae.
  - The clinician assesses the thigh–foot angle and the transmalleolar axis with the patient prone. Most commonly, the thigh–foot angle is abnormally positive (excessively turned out versus the thigh), whereas the transmalleolar axis (assessing tibial torsion) is normal.
  - The clinician determines whether the subtalar joint can be inverted to neutral (see Fig 2), although the calcaneal lengthening osteotomy can correct hindfoot valgus even in a rigid deformity.
- Radiographs must be taken with full weight bearing to correlate with the physical examination findings. AP and lateral views are required (see Fig 4). Oblique and Harris axial views of the foot can be added to confirm absence of a tarsal coalition. AP, mortise, and lateral ankle radiographs are useful to determine whether any of the valgus deformity is in the tibiotalar joint.
  - The clinician should discuss with the family the risks and complications of allograft versus autograft for the required tricortical (bicortical) iliac crest bone graft, as well as the possible need for a medial cuneiform plantar-based closing wedge osteotomy.
  - The need for this additional procedure can be accurately determined only intraoperatively after correction of the hindfoot and lengthening of the heel cord.
- Discussion about staged versus concurrent correction of bilateral deformities should include issues relating to the need for strict non-weight bearing on the operated foot or feet for 8 weeks. Most adolescents choose the correction of one foot at a time, with correction of the other foot 6 months later. This interval allows adequate rehabilitation for the operated foot to function comfortably while non-weight bearing on the second foot.

Positioning
- The patient is placed in the supine position with a folded towel under the ipsilateral buttock and prepared from iliac crest to toes. A sterile tourniquet is included if using autograft. If using allograft, only the lower extremity is prepared, and a nonsterile tourniquet is used.
Special equipment includes a narrow sagittal saw, smooth Steinmann pins, straight osteotomes, laminar spreader with smooth teeth, Joker elevators and narrow Crego retractors, and a mini-fluoroscope.

**Approach**
- A modified Ollier incision is used in a Langer skin line for the calcaneal lengthening osteotomy. The superficial peroneal and sural nerves are protected.

**CALCANEAL OSTEOTOMY EXPOSURE AND LATERAL SOFT TISSUE RELEASES**
- Make a modified Ollier incision in a Langer skin line from the superficial peroneal nerve to the sural nerve (TECH FIG 1A). Elevate the soft tissues from the sinus tarsi. Avoid exposure of, or injury to, the capsule of the calcaneocuboid joint.
- Release the peroneus longus and the peroneus brevis from their tendon sheaths on the lateral surface of the calcaneus (TECH FIG 1B).
- Resect the intervening tendon sheaths and, if large, the peroneal tubercle. Z-lengthen the peroneus brevis tendon. Do not lengthen the peroneus longus.
- Divide the aponeurosis of the abductor digiti minimi at a point about 2 cm proximal to the calcaneocuboid joint (TECH FIG 1C).
- Identify the interval between the anterior and middle facets of the subtalar joint with a Freer elevator. Insert

**TECH FIG 1** • A. Modified Ollier incision marked in a Langer skin line halfway between the tip of the lateral malleolus and the beak of the calcaneus (two dots), and extending from the superficial peroneal nerve (dotted line) to the sural nerve. B. The peroneus brevis (above) and the peroneus longus (below) have been released from their tendon sheaths. C. The soft tissue contents have been elevated from the isthmus of the calcaneus. The peroneus brevis is lengthened and the peroneus longus is retracted. The aponeurosis of the abductor digiti minimi is exposed for release. D–F. Finding the interval between the anterior and middle facets of the subtalar joint. D. A Freer elevator is inserted perpendicular to the lateral border of the calcaneus just proximal to the beak of the calcaneus. It makes contact with the middle facet. E. The Freer is rotated distally until the tip falls into the interval between the anterior and middle facets. F. This is confirmed with the mini-fluoroscope. (From Mosca VS. Calcaneal lengthening osteotomy for valgus deformity of the hindfoot. In: Tolo V, Skaggs D, eds. Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics. Philadelphia: Lippincott Williams & Wilkins, 2008.)
it into the sinus tarsi perpendicular to the lateral cortex of the calcaneus at the level of the isthmus (ie, the lowest point of the dorsal cortex in the sinus tarsi proximal to the beak and distal to the posterior facet) (TECH FIG 1D). The middle facet will be encountered.

- Slowly angle the Freer distally until it falls into the interval between the anterior and middle facets (TECH FIG 1E).
- Confirm that the Freer is in the interval using fluoroscopy (TECH FIG 1F).

- Replace the Freer with a curved Joker elevator. Place a second Joker elevator around the plantar aspect of the calcaneus in an extraperiosteal plane in line with the dorsal Joker.
- Remove the Jokers and prepare the exposures for the other procedures before performing the calcaneal osteotomy.

### MEDIAL SOFT TISSUE PLICATION EXPOSURE AND PREPARATION

- Make a longitudinal incision along the medial border of the foot starting at a point just distal to the medial malleolus and continuing to the base of the first metatarsal.
- Release the tibialis posterior from its tendon sheath. Cut the tendon in a Z-fashion, releasing its dorsal half from the navicular (TECH FIG 2A). The stump of tendon remaining attached to the navicular contains the plantar half of the fibers.
- Incise the talonavicular joint capsule from dorsal-lateral to plantar-lateral, including release of the spring ligament.
- Resect a 3–5 mm-wide strip of capsule from the medial and plantar aspects of this redundant tissue (TECH FIG 2B).

### ACHILLES TENDON OR GASTROCNEMIUS LENGTHENING

- Assess the equinus contracture by the Silfverskiöld test with the subtalar joint inverted to neutral and the knee both flexed and extended.
- Perform a gastrocnemius recession if 10 degrees of dorsiflexion can be achieved with the knee flexed, but not with it extended.
- Perform an open or percutaneous Achilles tendon lengthening if 10 degrees of dorsiflexion cannot be obtained even with the knee flexed (TECH FIG 3).

TECH FIG 2 • A. The tibialis posterior is cut in a Z-fashion, releasing the dorsal slip from the navicular.
B. The talonavicular joint capsule is released from dorsolateral to plantar-lateral, including release of the spring ligament. A 3- to 5-mm-wide strip of redundant capsule is resected from its plantar-medial aspect. (From Mosca VS. Calcaneal lengthening osteotomy for valgus deformity of the hindfoot. In: Tolo V, Skaggs D, eds. Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics. Philadelphia: Lippincott Williams & Wilkins, 2008.)

TECH FIG 3 • The Achilles tendon or the gastrocnemius tendon is lengthened based on the results of the Silfverskiöld test. (From Mosca VS. Calcaneal lengthening osteotomy for valgus deformity of the hindfoot. In: Tolo V, Skaggs D, eds. Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics. Philadelphia: Lippincott Williams & Wilkins, 2008.)
CALCANEAL OSTEOTOMY AND BONE GRAFT INTERPOSITION

Replace the Joker elevators, or Crego retractors, both dorsal and plantar to the isthmus of the calcaneus, meeting in the interval between the anterior and middle facets of the subtalar joint.

Perform an osteotomy of the calcaneus using a sagittal saw or osteotome (TECH FIG 4A).

It is an oblique osteotomy from proximal-lateral to distal-medial that starts about 2 cm proximal to the calcaneocuboid joint (at the lowest point of the calcaneus proximal to the beak) and exits between the anterior and middle facets (TECH FIG 4B).

It is a complete osteotomy through the medial cortex. Cut the plantar periosteum and long plantar ligament (not the plantar fascia) under direct vision if necessary (ie, if these soft tissues resist distraction of the bone fragments).

Insert a 2-mm smooth Steinmann pin retrograde from the dorsum of the foot passing through the cuboid, across the center of the calcaneocuboid joint, and stopping at the osteotomy (TECH FIG 4C,D).

This is performed with the foot in the original deformed (everted) position before the osteotomy is distracted. By so doing, the pes acetabulum (navicular, spring ligament, anterior facet of calcaneus) will be maintained intact and the distal fragment of the calcaneus will not subluxate dorsally on the cuboid during distraction of the osteotomy.

Insert a 0.062-inch smooth Steinmann pin from lateral to medial in both of the calcaneal fragments immediately adjacent to the osteotomy. These will be used as joysticks to distract the osteotomy at the time of graft insertion.

Place a smooth-toothed lamina spreader in the osteotomy and distract maximally, trying to avoid crushing the bone (TECH FIG 4E).

Assess deformity correction of the hindfoot clinically and using mini-fluoroscopy. The deformity is corrected when the axes of the talus and first metatarsal are colinear in both the AP and lateral planes (TECH FIG 4F,G).

TECH FIG 4 • A. With Joker and Crego retractors surrounding the isthmus of the calcaneus and meeting in the interval between the anterior and middle facets, the osteotomy is performed with a sagittal saw in line with the retractors. B. Fluoroscopic appearance of the osteotomy in the proper location. C. With the foot in the original flat and everted position, a 2-mm smooth wire is inserted retrograde from the dorsum of the foot through the middle of the calcaneocuboid joint, stopping at the osteotomy. D. Position of the wire at the calcaneocuboid joint is confirmed with fluoroscopy. E. Steinmann pins in the proximal and distal calcaneal fragments can be used as joysticks to distract the osteotomy during graft insertion. The lamina spreader is used to determine the necessary graft size. F,G. Fluoroscopy can help confirm the required graft size by showing, with the lamina spreader opened, when the talonavicular joint is aligned and the talus and first metatarsal axes are colinear. (continued)
MEDIAL SOFT TISSUE Plication

- Plicate the talonavicular joint capsule plantar-medially, but not dorsally (TECH FIG 5A).

- Measure the distance between the lateral cortical margins of the calcaneal fragments. This is the lateral length dimension of the trapezoidal iliac crest graft that will be obtained either from the child's iliac crest or from the bone bank.
  - The trapezoid should taper to a medial length dimension of 20% to 30% of the lateral length (TECH FIG 4H).
  - The calcaneal lengthening osteotomy is a distraction wedge rather than a simple opening wedge, as the center of rotation is the center of the talar head, not the medial cortex of the calcaneus.
  - Remove the laminar spreader and use the Steinmann pin joysticks to distract the calcaneal fragments.
  - Insert and impact the graft with the cortical surfaces aligned from proximal to distal in the long axis of the foot (TECH FIG 4I). This will place the cancellous bone of the graft in direct contact with the cancellous bone of the calcaneal fragments.
  - Advance the previously inserted 2-mm Steinmann pin retrograde through the graft and into the proximal calcaneal fragment. Bend the pin at its insertion site on the dorsum of the foot for ease of retrieval in the clinic.
  - No additional fixation is required. In fact, were the pin not needed to prevent subluxation at the calcaneocuboid joint, no graft fixation would be needed.
  - Repair the peroneus brevis tendon with an absorbable suture after a 5- to 7-mm lengthening.

- Advance the proximal slip of the tibialis posterior about 5 to 7 mm through the distal stump of the tendon using a Pulvertaft weave with an absorbable suture material (TECH FIG 5B,C).
**MEDIAL CUNEIFORM OSTEOTOMY**

- Assess the forefoot for structural supination deformity by holding the heel with the ankle in neutral dorsiflexion and viewing in line with the axis of the foot from toes to heel.
- Visualize the plane of the metatarsal heads in relation to the long axis of the tibia (TECH FIG 6A).
- Also assess the dorsal-plantar mobility of the first metatarsal–medial cuneiform joint.
  - A plantarflexion osteotomy of the medial forefoot–midfoot is required if the metatarsals are supinated.
- A plantar-based closing wedge osteotomy in the midportion of the medial cuneiform is an effective procedure to correct this deformity (TECH FIG 6B). The plantar base of the resected wedge generally measures 4 to 7 mm in length.
- The osteotomy is closed and internally fixed with a 0.062-inch smooth wire staple inserted from plantar to dorsal.
- Check to ensure correction of the forefoot deformity (TECH FIG 6C).

**TECH FIG 6 • A.** The rotational alignment of the forefoot is assessed after correction of the hindfoot deformity and the heel cord contracture. If, as in this case, the forefoot is supinated, an osteotomy of the forefoot is required. **B.** A medial cuneiform plantar-based closing wedge osteotomy will correct the supination deformity of the forefoot. **C.** Forefoot deformity has been corrected. (From Mosca VS. Calcaneal lengthening osteotomy for valgus deformity of the hindfoot. In: Tolo V, Skaggs D, eds. Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics. Philadelphia: Lippincott Williams & Wilkins, 2008.)

**PEARLS AND PITFALLS**

**Indications**
- Flexible flatfoot is a normal foot shape that rarely causes pain or disability. Associated contracture of the Achilles or gastrocnemius tendon may cause pain that interferes with the enjoyment of desired activities. Pain that cannot be relieved by prolonged attempts at conservative management is the absolute indication for surgery.

**Calcaneal osteotomy location**
- The surgeon should try to find the interval between the anterior and middle facets of the subtalar joint to create an extra-articular osteotomy, although only about 60% of individuals have separate facets.

**Lateral soft tissue management**
- The surgeon lengths the peroneus brevis and the aponeurosis of the abductor digiti minimi to facilitate distraction of the bone fragments. However, the peroneus longus is not lengthened. The latter is the plantarflexor of the medial forefoot. Lengthening the lateral bony column of the foot results in a relative shortening of the peroneus longus, which, in turn, plantarflexes the medial forefoot to help correct the supination deformity.

**Calcaneocuboid joint protection**
- Inadvertent subluxation of the calcaneocuboid joint when the calcaneal osteotomy is distracted can be prevented by inserting a retrograde smooth Steinmann pin across the middle of the joint before the fragments are distracted.

**Forefoot supination deformity**
- The surgeon must not ignore the forefoot deformity. It is assessed intraoperatively after correction of the hindfoot deformity. Significant uncorrected residual forefoot supination deformity will create a bipod, rather than the normal tripod, foot with lack of support under the first metatarsal head. If untreated, this may lead to recurrence of valgus deformity of the hindfoot. A plantar-based closing wedge osteotomy of the medial cuneiform is performed if necessary.

**Achilles or gastrocnemius contracture**
- This is the deformity that changed a normal flexible flatfoot into a painful flatfoot. The contracted tendon should be lengthened.
POSTOPERATIVE CARE

- The incisions are closed with absorbable sutures.
- A well-padded short-leg non-weight-bearing cast is applied and bivalved to allow for swelling overnight.
- Radiographs in the cast are obtained (FIG 5).
- The patient is discharged from the hospital the following day after the bivalved cast is overwrapped with cast material.
- The patient is immobilized in a below-knee cast and is not permitted to bear weight on the operated extremity for 8 weeks.
- At 6 weeks, the cast is removed to obtain simulated standing AP and lateral radiographs and to remove the Steinmann pin. Another below-the-knee non-weight-bearing cast is applied.
- On removal of this cast 2 weeks later, final simulated standing AP and lateral radiographs are obtained.
- Over-the-counter arch supports are used indefinitely.
- Physical therapy is rarely needed.

OUTCOMES

- The calcaneal lengthening osteotomy has the best-reported long-term results for any procedure that has been used to correct flatfoot deformity.
- It has been shown to correct all components of even severe valgus–eversion deformity of the hindfoot, restore function of the subtalar complex, relieve symptoms, and, at least theoretically, protect the ankle and midtarsal joints from early degenerative arthrosis by avoiding arthrodesis.

FIG 5 • Final radiographs in the bivalved cast. A. On the AP view, note the correction of the external rotation deformity at the talonavicular joint as also assessed by the talo-first metatarsal angle. B. The lateral view demonstrates dorsiflexion of the talus, alignment at the talonavicular joint, correction of the talo-first metatarsal angle, and normalization of the calcaneal pitch. (From Mosca VS. Calcaneal lengthening osteotomy for valgus deformity of the hindfoot. In: Tolo V, Skaggs D, eds. Master Techniques in Orthopaedic Surgery: Pediatric Orthopaedics. Philadelphia: Lippincott Williams & Wilkins, 2008.)

COMPLICATIONS

- Subluxation of the calcaneocuboid joint when the calcaneal osteotomy is distracted may occur. This can be avoided by lengthening the peroneus brevis, releasing the aponeurosis of the abductor digiti minimi, releasing the plantar calcaneal periosteeum and long plantar ligament (not the plantar fascia), and pinning the calcaneocuboid joint in a retrograde fashion before the osteotomy is distracted.
- Deformity correction may be incomplete. This can be avoided by performing the procedures listed just above and by releasing the entire dorsal talonavicular joint capsule. The surgeon should use a graft that is large enough to make the axes of the talus and the first metatarsal colinear in both planes. This is confirmed with intraoperative imaging, such as mini-fluoroscopy.
- Persistent equinus can be avoided by lengthening the contracted Achilles tendon or gastrocnemius tendon.
- Persistent supination deformity of the forefoot on the hindfoot can be avoided by identifying it after the calcaneal lengthening and heel cord lengthening. It is treated with a medial cuneiform plantar-based closing wedge osteotomy.

REFERENCES

DEFINITION
- Shortening of the Achilles tendon, gastrocsoleus complex (triceps surae), or both results in an equinus (plantarflexed) position of the calcaneus relative to the tibia.
- An equinus deformity is either congenital or acquired and can be dynamic or rigid.
  - A dynamic deformity will correct with passive manipulation.
  - A rigid, or fixed, deformity does not correct.
- Achilles or gastrocnemius contracture often occurs in combination with other soft tissue contractures.

ANATOMY
- The two heads of the gastrocnemius originate on the posterior aspect of the medial and lateral condyles of the distal femur.
  - The muscle fibers terminate at the muscle–tendon junction at the midcalf.
  - From here, the Achilles tendon is joined by tendon fibers from the posterior aspect of the soleus as the tendon courses distally.
  - The tendon is broad proximally and then becomes rounded at the midsection when it undergoes a 90-degree internal rotation before its insertion on the posterosuperior third of the calcaneus.
  - The rotation causes the medial fibers of the midtendon to insert on the posterior portion of the calcaneus (FIG 1).
- The insertion footprint is delta-shaped, and a small portion of the fibers course distally to meet the origin of the plantar fascia.
- The blood supply of the Achilles tendon is limited.
  - The proximal portion is supplied by branches from within the gastrocnemius muscle.
  - The distal portion is supplied by branches from the tendon–bone interface.
  - There is no true synovial sheath. Instead, the surrounding paratenon, comprising loose connective tissue, supplies the rest of the blood supply via branches from the posterior tibial artery and, to a lesser degree, the peroneal artery.
  - There are two synovial bursae at the Achilles tendon insertion site.
    - One is subcutaneous, located between the skin and tendon, and the other is deep, located between the tendon and the calcaneus.

PATHOGENESIS
- The pathogenesis of congenital equinus is poorly understood and it is often associated with other limb deformities, such as clubfoot or congenital vertical talus.
- Acquired equinus deformity secondary to cerebral palsy results from muscle spasticity or imbalance, leading to subsequent contracture of the Achilles tendon and gastrocsoleus complex.
  - Muscle imbalance and spasticity in spastic diplegic cerebral palsy often results in equinoplanovalgus deformity.
  - Muscle imbalance and spasticity in spastic hemiplegic cerebral palsy often results in equinus or equinovarus deformity.
  - Compensatory balance mechanisms to help maintain ambulation in patients with Duchenne muscular dystrophy also may result in equinus deformity.
- Posttraumatic equinus can also be a result of severe burns and posterior scar contracture, postburn positioning, anterior leg muscle loss, or continued tibial growth in a rigid scar.
  - Talocrural and subtalar capsular adhesions and an abnormal tibiotalar articulation may also contribute to loss of dorsiflexion and equinus deformity.

NATURAL HISTORY
- Fixed equinus deformity will not correct spontaneously and requires prescribed stretching, surgical intervention, or both.
- Equinus associated with cerebral palsy is progressive. Despite both conservative and surgical treatments, the deformity can recur due to persistent spasticity, muscle imbalance, or limb growth.
- Equinus deformity results in abnormal gait because of altered ankle range of motion and decreased ankle plantarflexion moment during terminal stance. It can result in chronic pain, poorly fitting footwear, callosities on the plantar forefoot, and possible skin ulceration in patients with altered sensation.
PATIENT HISTORY AND PHYSICAL FINDINGS

- Birth history may reveal gestational or perinatal complications, such as traumatic brain injury or global hypoxic events, which are risk factors for cerebral palsy.
- Family history may reveal an inherited neuromuscular disease or idiopathic toe walking.
- A delay in gross motor milestones may suggest the presence of a static neurologic disorder such as cerebral palsy, while regression of gross motor function may suggest a progressive neuromuscular disease such as muscular dystrophy or Rett syndrome.
- The age of equinus deformity onset will depend on the type and severity of the underlying condition.
- Posttraumatic equinus, particularly a burn, should prompt questions regarding severity of the soft tissue loss, type of treatment, period of immobilization, and current problems with skin ulceration to assess the severity of scarring and underlying skin quality.
- Physical examination should include a thorough examination of the entire lower extremities to look for associated deformities at the hip, knee, hindfoot, and forefoot.
- The patient is examined supine on the examination table. It is important that the table has a hard surface so as not to mask any other contractures.
- Ankle range of motion: Absence of dorsiflexion beyond neutral is ankle equinus.
- Silfversköld test: A positive test indicates isolated gastrocnemius contracture. This is present if ankle equinus is present with the knee extended, but improves with knee flexion.
- Palpation of Achilles tendon: A tight tendon suggests spasticity of the gastrocsoleus complex or contracture of the Achilles tendon.
- Palpation of posterior tibial and peroneal tendons: Taut tendons suggest additional contracture or spasticity of the involved musculotendinous units contributing to the ankle equinus contracture.
- Ankle clonus: More than two beats of clonus is abnormal and indicates gastrocsoleus spasticity or an upper motor neuron lesion.
- If the child is ambulatory, the clinician should observe the gait in a hallway or large area where the patient can both walk and run.
- Socks, shoes, and clothing that extends below the knee are removed.
- Hindfoot alignment is best observed from behind.
- The foot progression angle (axis of the foot to the axis of progression) and any associated coronal plane abnormalities, such as scissoring (excessive hip adduction during gait), knee progression angle, and pelvic rotation, are best observed from the front.
- Ankle equinus and any associated sagittal plane abnormalities, such as a crouch gait (hip and/or knee flexion contracture) or a stiff-knee gait (decreased knee range of motion during swing phase), are best observed from the side.
- In mild equinus, the normal heel-to-toe gait of the plantargrade foot will be replaced with early lift-off during stance. Subtle deformity in patients with cerebral palsy is often unmasked by asking the patient to run. In severe equinus, the heel will not make contact during heel-strike.
- Equinovarus or equinoplanovalgus deformity will cause initial contact during gait to occur on either the lateral or medial border of the foot, respectively. There may be a callus or foot pain at the area of initial contact.
- The alignment and passive range of motion of the lumbar sacral spine, pelvis, hips, and knees must also be tested, since equinus may be a functional compensation for coexistent contractures.
- Associated muscle spasticity or contracture in cerebral palsy should be diagnosed with the appropriate physical examination maneuvers described in the relevant chapters.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Anteroposterior (AP) and lateral weight-bearing radiographs of the affected ankle should be obtained.
- Ossification centers of the talus, calcaneus, and cuboid are present at infancy. The navicular does not appear until age 3 to 4 years.
- Equinus deformity will result in a decreased lateral tibial-calcaneal angle. Normal values range from 25 to 60 degrees. It can be difficult to measure this angle in young children with a partially ossified calcaneus.
- Although usually associated with hindfoot varus, equinus deformity can also result in a decreased lateral talocalcaneal angle (intersection of a line through the longitudinal axis of the talus and a line along the plantar surface of the calcaneus; FIG 2). The normal range is 25 to 55 degrees.
- Bony abnormalities, such as a flattened talar dome or anterior talar neck and anterior distal tibial osteophytes, can also contribute to ankle equinus contracture.
- Arthrogram may be useful to compare talocrural and subtalar motion during ankle dorsiflexion and plantarflexion to reveal capsular contractures contributing to restricted dorsiflexion and equinus deformity.6

DIFFERENTIAL DIAGNOSIS

- Congenital equinus
- Talipes equinovarus (clubfoot)
- Planovalgus
- Congenital vertical talus
- Arthrogryposis
- Tibial hemimelia
- Acquired equinus
- Neuromuscular
  - Cerebral palsy
  - Myelomeningocele

FIG 2 • Measurement of the lateral talocalcaneal angle. The normal range of 25 to 55 degrees is decreased in equinus.
Charcot-Marie-Tooth
Spinal muscular atrophy
Sacral agenesis
Rett syndrome or other genetic neuromuscular diseases
Posttraumatic
Posterior scar contracture
Posttrauma positioning
Anterior leg muscle loss
Continued tibial growth in a rigid scar
Other
Idiopathic toe walking
Juvenile arthropathy

NONOPERATIVE MANAGEMENT
Many children with equinus deformity secondary to a contracture of the Achilles tendon or gastrocnemius–soleus complex can be successfully managed with nonoperative treatment.
This is typically performed with serial casting for 3 to 6 weeks or more to achieve neutral sagittal alignment.
The success of nonoperative management depends on the age of the patient, the severity of the deformity, and the cause of the equinus.
In patients with equinus and cerebral palsy, early surgery may have an unpredictable outcome, with high rates of recurrence.
For this reason, surgery is often delayed with nonoperative treatments until after age 6 years.
Physical therapy for Achilles tendon stretching helps correct and maintain correction of equinus deformity.
The efficacy of stretching is likely dependent on the duration and frequency of stretching.
Use of an ankle–foot orthosis (AFO) in patients with cerebral palsy and dynamic equinus is a useful adjunct to nonsurgical management.
Botulinum toxin A (BtA) has been shown to be as effective as serial casting, with fewer side effects and more prolonged benefit.
Serial casting and physical therapy are recommended as an adjunct to BtA injections.
Oral medications for muscle relaxation, such as baclofen, diazepam, dantrolene sodium, and tizanidine, can be helpful in selected patients with cerebral palsy if generalized reduction in tone is desired.

SURGICAL MANAGEMENT
Indications for surgical management include fixed ankle equinus that exists with the knee flexed as well as extended and that also interferes with normal gait.
Clinical difficulties may include pain with weight bearing, toe walking, callosities on the plantar forefoot, poorly fitting orthoses, or plantar midfoot pain.
Surgical management of fixed ankle equinus in knee extension that disappears in knee flexion should consist of surgery to the gastrocnemius fascia alone.
Especially in patients with cerebral palsy, surgical management of ankle equinus should include concurrent treatment of all pelvic and lower extremity deformities, particularly hamstring contractures.

The open Achilles Z-lengthening procedure uses the same technique of a sliding Achilles lengthening.
We prefer the supine position for patients undergoing isolated tendo Achilles lengthening.
A thigh tourniquet can be used.
The leg is prepared sterilely from the tourniquet distally.
If other concurrent soft tissue tendon lengthenings are to be performed, the patient is positioned and prepared according to the additional procedures.

Preoperative Planning
The quality of the overlying skin will be crucial for successful wound healing and should be considered during the preoperative planning phase.
Inadequate skin elasticity may require incomplete correction and staged surgery or staged casting in the postoperative period.
In severe posttraumatic cases, tissue loss and significant scarring may require additional tissue transfer procedures.
In cerebral palsy patients with severe spasticity, examination under anesthesia can help determine if equinus deformity is dynamic or fixed, since paralytic medications during anesthesia eliminate spasticity.

Positioning
The patient can be positioned either prone or supine.
The prone position allows improved access to the tibiotalar and subtalar joint capsules but requires careful padding to the hips and knees (FIG 3).
We prefer the supine position for patients undergoing isolated tendo Achilles lengthening.
The prone position allows improved access to the tibiotalar and subtalar joint capsules but requires careful padding to the hips and knees (FIG 3).
For sliding procedures, a modified approach that exposes only the transected portion of the tendon can also be performed.
To avoid postoperative wound complications, a longitudinal incision along the anteromedial border of the Achilles tendon is recommended.
This decreases the risk of wound dehiscence, since the thinnest portion of the overlying skin is directly posterior to the tendon and should remain intact.
For sliding procedures, a modified approach that exposes only the transected portion of the tendon can also be performed.

The open sliding Achilles lengthening technique, first described by White,9 is performed with partial transections at the (1) proximal and medial and (2) distal and anterior portions of the tendon. The 90-degree rotation of the tendon fibers between the transected areas maintains continuity of the tendon fibers as the tendon is lengthened (FIG 4A).
The modified open sliding Achilles lengthening technique decreases the size of the skin incision but uses the same technique of a sliding Achilles lengthening.
The open Achilles Z-lengthening procedure uses the same incision and closure as the modified approach. Here, the entire tendon is divided in a Z-fashion (FIG 4B), and the two sides or ends of the tendon are sutured to each other.
OPEN SLIDING ACHILLES LENGTHENING

- The incision is made along the anteromedial border of the Achilles tendon.
- The skin incision begins just proximal to the calcaneal insertion (TECH FIG 1A) and continues proximally to the proximal extent of the tendon.
- At the proximal portion of the incision, sharply divide the subcutaneous fat in line with the incision.
- There are no neurovascular structures at risk here and the incision can be directed deeply until the paratenon sheath surrounding the tendon has been fully incised to form a small opening.
- The sheath comprises multiple thin layers, and full division of these layers is apparent once the gleaming white tissue of the tendon is encountered and the surgeon’s forceps can no longer grasp any intervening tissue.
- Using round-tipped dissecting scissors directed distally and laterally and aligned longitudinally with the tendon,
pass one blade inside the paratenon and cut both the subcutaneous fat and sheath together until the calcaneal insertion is reached.
- This maintains attachment of the sheath to the subcutaneous fat, preserving the blood supply and providing closure of the sheath with approximation of the subcutaneous fat during wound closure.
- The tendon should now be completely exposed.
- Insert a new blade, cutting edge inferior, just proximal to the calcaneus in the coronal plane between the anterior two thirds and posterior one third of the distal tendon (TECH FIG 1B).
- Rotate the blade so the cutting edge is anterior and divide the anterior two thirds of the tendon transversely.
- Identify the most proximal portion of the tendon that has been exposed.
- Again, transversely divide the medial two thirds of the tendon, taking care to avoid any underlying muscle fibers of the soleus (TECH FIG 1C).

MODIFIED OPEN SLIDING ACHILLES LENGTHENING
- Identify the anteromedial border of the Achilles tendon as described previously and, with a pen, draw the length of incision as if planning a fully open procedure.
- This helps ensure alignment of the two incisions and avoids gaping of the wound after dorsiflexion and subsequent uneven tensioning of the skin.
- Using a skin blade, create two short longitudinal incisions at the distal and proximal ends of the drawn line (TECH FIG 2).
- As previously described, sharply dissect the overlying tissues to reach the Achilles tendon at the proximal and distal incisions and partially divide the tendon at each area of exposure.
- As for the original open lengthening technique, slowly dorsiflex the foot with gentle pressure to cause the divided portions of the tendon to slide past one another until 10 degrees of dorsiflexion is achieved.
- Close the subcutaneous tissues and skin and apply a short- or long-leg cast as described previously.

OPEN ACHILLES Z-LENGTHENING
- Once the entire tendon has been exposed through the anteromedial approach, gently retract the most distal and medial tissues anteriorly to protect the underlying neurovascular structures.
- Align a new no. 15 blade longitudinally with the tendon fibers at the midpoint of the tendon in the sagittal plane. Introduce the blade deeply into the tendon until there is a discernable release in resistance, signifying complete transection through the tendon.
- Alternately, a small osteotome may be introduced along the anterior border of the tendon, and the blade can be carried safely through the entire tendon until metal-on-metal contact.
- Carry the incision distally until the calcaneal insertion is reached (TECH FIG 3A).
- Without removing the blade, rotate the blade medially 90 degrees and with a slight sawing motion, transversely divide the medial portion of the tendon.
- Once this is achieved, retraction of the medial structures can be safely released.
- Return the blade to the proximal starting point and extend the division proximally until an adequate portion of the tendon is involved.
- This is usually about two thirds of the Achilles tendon but will ultimately depend on the desired lengthening and overlap between the two ends.
- Take care to stay along the midline of the tendon.
Complete the proximal division of the tendon laterally in this transverse plane (TECH FIG 3B).

The entire tendon should now be divided in a Z-fashion (TECH FIG 3C).

Dorsiflex the ankle to neutral. Under moderate tension, reapproximate the sides of the tendon with a braided nonabsorbable suture.

This can be done with multiple interrupted simple or vertical mattress sutures (TECH FIG 3D).

Alternately, the overlapping ends of the tendon can be excised for approximation of the ends.

Multiple intratendinous and epitendon suture techniques are acceptable for reapproximation.

The intratendinous technique reduces exposed suture and diminishes inflammatory reaction around the suture, and is recommended.

The simplest of these is the modified Kessler suture (locking loops of the core suture; TECH FIG 3E).

Apply either a long- or short-leg plaster cast as discussed above.

**TECH FIG 3**

**A.** Full exposure of the Achilles tendon has been achieved and the initial transection in the sagittal plane, dividing the medial and lateral halves of the tendon, has been performed with a blade. **B.** The entire tendon is exposed and is being transected in a Z-fashion. **C.** The ankle is dorsiflexed to the appropriate position and the overlapping tendon is noted. **D.** The desired amount of overlapping tendon has been joined with vertical mattress sutures. **E.** Alternately, the tendons can be reapproximated end to end. After Z-lengthening, the remaining overlapping tendon has been removed and the ends of the tendon are joined with a nonabsorbable suture and a modified Kessler repair.

### Pearls and Pitfalls

**Failure to address coexistent contractures**

- All associated joint contractures, particularly in cerebral palsy, should be addressed to achieve optimal surgical results.

**Surgical indications**

- Patients with a positive Silfverskiöld test should not be treated with an Achilles lengthening.

**Overlengthening**

- In an open Z-lengthening, repairing the tendon with the ankle in dorsiflexion or under inadequate tension can lead to overlengthening.
- In a sliding lengthening, dorsiflexing the ankle beyond 10 degrees can lead to overlengthening.

**Wound healing problems**

- The paratenon should not be dissected free from the overlying subcutaneous tissue posteriorly.
- Posterior skin contractures should be treated intraoperatively with tissue transfer procedures or postoperatively with undercorrection and serial casting.

**Inadequate correction**

- Severe equinus deformity often requires a concurrent release of the posterior subtalar and tibiotalar joint capsules; lengthening of the posterior tibial and peroneal tendons; or both.
- Failure to extend the Z-lengthening incision to the most proximal portion of the tendon can lead to insufficient length of tendon at repair and therefore to undercorrection.
- In a sliding lengthening, failure to dorsiflex the ankle to 10 degrees with the knee extended and the subtalar joint inverted can result in undercorrection.

**Revision surgery**

- The normal 90-degree spiral architecture of the tendon is altered with surgery, and an open Z-lengthening procedure is indicated for revision surgery.
POSTOPERATIVE CARE
- Adequate pain control in the acute postoperative setting is imperative. This is both to promote the child’s comfort and to reduce additional muscle spasms, which may alter the desired surgical correction.
- Since children with neuromuscular diseases may have significant communicative barriers, pain should be presumed to be present and should be treated with both morphine derivatives and muscle relaxants.
- The limb should be elevated as much as possible for 2 or 3 days until acute swelling resolves.
- The child can then become ambulatory and weight bearing as tolerated if a sliding tendon lengthening was performed.
- Patients undergoing open Z-lengthening should remain non-weight bearing in a cast until tendon healing is sufficient (6 weeks).
- Once the cast is permanently removed, the child needs postoperative physical therapy or use of an AFO, as dictated by the diagnosis.

OUTCOMES
- Surgical lengthening results in gains in dorsiflexion, from a preoperative average of 25 degrees of plantarflexion to 8 degrees of dorsiflexion, without significant changes in the arc range of motion.
- Correction is maintained in 80% to 90% of patients for at least 7 years postoperatively.4

COMPLICATIONS
- Calcaneovalgus deformity occurs in less than 2% of open Achilles tendon lengthenings.
- Recurrent deformity is common in neuromuscular diseases owing to continued spasticity and normal longitudinal tibial growth.
- After surgical correction, 18% of children with diplegia and 41% of those with hemiplegia will experience recurrence.
- Ambulatory patients maintain correction better than non-ambulatory patients.
- Recurrence is also more frequent in children 4 years or younger.7
- Wound dehiscence and necrosis are infrequent and the incidence is not well reported.
- These can be devastating, however, and should remain a matter of concern as potential complications.

REFERENCES
DEFINITION
- The equinovarus deformity involves hindfoot equinus and varus and results from imbalance between inversion (tibialis posterior, tibialis anterior, or both) and eversion of the foot.
- The deformity is most common in spastic hemiplegia but may also be seen in patients with diplegic and quadriplegic involvement.
- The deformity may interfere with ambulation, orthotic wear, or both.

ANATOMY
- The tibialis posterior muscle originates from the posterolateral aspect of the tibia, the interosseous membrane, and the medial fibula.
  - Although the main insertion is into the tuberosity of the navicular, fibers also insert onto the cuneiforms, the second through fourth metatarsals, the cuboid, and the sustentaculum tali.
- The gastrocnemius muscle originates from the posterior surface of the distal femur, and its tendon blends with the tendon of the soleus muscle to form the Achilles tendon, which then inserts on the posterior tuberosity of the calcaneus.
- The soleus muscle takes origin from the posterior portion of the upper third of the fibula, the fibrous arch between the tibia and the fibula, and the posterior aspect of the tibia.
  - The broad tendinous portion along the posterior aspect of the muscle joins with the gastrocnemius tendon to form the Achilles tendon.

PATHOGENESIS
- The deformity results from muscle imbalance between plantarflexion–inversion (strong) and dorsiflexion–eversion (weak).
  - Spasticity of the tibialis posterior, the tibialis anterior, or both may be responsible for the imbalance.

NATURAL HISTORY
- The deformity is initially dynamic, with a full range of motion on physical examination.
  - A myostatic contracture often develops over time, evidenced by the inability to achieve a full passive range of motion.
  - Tethering of growth may subsequently result in structural bony deformities such as hindfoot varus.
- The equinovarus deformity may result in pathologic changes in both the stance and swing phases of gait, including impaired clearance during swing phase, the inability to preposition the foot in terminal swing, and loss of stability during stance phase.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients present with progressive gait disturbance, with or without pain, and may have difficulty wearing orthotics.
- Pain is due to the abnormal stress distribution on the plantar surface of the foot and is commonly experienced over the distal fifth metatarsal and the lateral border of the foot. Calluses may be observed laterally.
- Recurrent ankle sprains may occur as the hindfoot rolls into varus.
- In addition to a comprehensive examination of the spine and both extremities, the physical examination focuses on observational gait analysis, the presence of and degree of spasticity in the individual muscle groups, the range of motion (active and passive) of the foot and ankle, and the selectivity of motor control.
- Observational gait analysis focuses on the alignment of the foot and ankle during both the swing and stance phases of gait.
  - During swing phase, the foot is inverted and plantarflexed, which impairs clearance.
  - The inability to maintain the foot in neutral plantarflexion–dorsiflexion during mid-swing may be due to muscle weakness (tibialis anterior), muscle spasticity (tibialis anterior or posterior, gastrosoleus), or a fixed equinovarus deformity.
  - There is inadequate prepositioning of the foot for weight acceptance during terminal swing.
  - Initial contact often occurs over the lateral forefoot (no heel contact), or over the lateral border of the foot, and the foot rolls into varus, which interferes with stability during stance phase.
  - The equinovarus deformity may also contribute to in-toeing (internal foot progression angle).
- The presence and degree of spasticity should be documented.
  - The most common system for grading is the modified Ashworth scale. Each muscle is tested by gentle stretch; for example, spasticity of the tibialis posterior is assessed by everting the foot, while the gastrosoleus complex is assessed by dorsiflexion.
  - The strength of individual muscle groups should be graded if possible.
- Testing the passive range of motion determines whether the deformity is dynamic (full passive range of motion) or whether there is a myostatic component (restriction of passive range of motion).
  - While bench examination provides a useful estimate of motion, an examination under anesthesia provides the most accurate evaluation, as spasticity is eliminated. Such an examination is always performed at the time of surgery to finalize the treatment plan.
For patients with an equinovarus deformity, the examination focuses on the degree of passive eversion and dorsiflexion. Equinus contracture is often limited to the gastrocnemius muscle but may also involve the soleus muscle.

The Silverskiold test evaluates the contribution of each component of the gastrosoleus complex to an equinus contracture, and the amount (in degrees) of passive dorsiflexion is quantified with the knee both flexed and extended. The degree of passive dorsiflexion with the knee extended indicates the absolute magnitude of contracture from the gastrocnemius and soleus. Flexion of the knee relaxes the gastrocnemius muscle and allows the contribution of the soleus to be quantified.

Selectivity of motor control is commonly impaired in children with cerebral palsy, and the distal motor groups are more involved than the proximal groups.

Selectivity is tested by asking the patient to contract an isolated muscle group against resistance.

If the patient can isolate the muscle and no “overflow” movement is observed in other muscle groups of the same limb, then adequate selectivity is present.

Most commonly, movements of more than one muscle group, or the entire limb, are elicited when testing individual muscle groups.

IMAGING AND OTHER DIAGNOSTIC STUDIES

While imaging studies are not routinely obtained, plain radiographs of the foot may be helpful in the presence of a fixed deformity.

Weight-bearing anteroposterior (AP) and lateral views are reviewed, and a Harris heel view may be considered to evaluate the degree of hindfoot varus in the weight-bearing position.

Instrumented motion analysis (gait analysis) is used in many centers to assist with surgical decision making.

Slow-motion video is an important component of the assessment and supplements the findings on observational gait analysis.

Dynamic electromyelography (EMG) monitors the electrical activity of the tibialis posterior and tibialis anterior throughout the gait cycle, determining whether individual muscles act out of phase or whether they are continuously active throughout the gait cycle (most common).

While a surface electrode may be used to assess the tibialis anterior, monitoring of the tibialis posterior requires insertion of a fine-needle electrode.

A recent study determined that the deformity was due to the tibialis posterior in 33%, the tibialis anterior in 34%, or both (31%).

The hindfoot varus usually occurs in both the stance and swing phases of gait.

Findings on pedobarography include increased pressure across the lateral midfoot, decreased pressure on the heel at the time of initial contact, and increased pressure on the lateral border of the foot throughout stance phase.

NONOPERATIVE MANAGEMENT

Specific aspects within a comprehensive physical therapy program include stretching exercises to maintain or improve range of motion and strengthening exercises to reduce dynamic muscle imbalance.

An ankle-foot orthosis is often required to maintain alignment of the ankle and hindfoot during ambulation.

The orthotic facilitates clearance during swing phase by maintaining the foot in a neutral position, prepositions the foot for initial contact with the ground, and promotes stability during stance phase.

Night splinting may help to prevent myostatic contracture.

Injection of botulinum toxin A (Botox or Dysport) into the tibialis posterior, the gastrocsoleus, or both results in a reversible chemical denervation that decreases spasticity for about 3 to 6 months.

In addition to reducing dynamic muscle imbalance, a temporary reduction in spasticity may facilitate stretching exercises, improve bracing tolerance, and delay the need for surgical intervention.

SURGICAL MANAGEMENT

Surgical treatment of the spastic equinovarus foot is offered when the deformity impairs ambulation, interferes with braking, or both.

Recent evidence suggests that the recurrence rate may be higher if the procedure is performed before 8 years of age, so it may be beneficial to delay split tendon transfer beyond this age if possible.

Lengthening of the tibialis posterior muscle may be adequate for mild deformities.

Techniques include a distal Z-lengthening of the tendon and an intramuscular recession proximally.

The goal of tendon transfer is to balance the muscle forces across the hindfoot to maintain a neutral position during the swing and stance phases of gait.

A split tendon transfer is preferred as transfer of the entire tendon is associated with a significant risk of overcorrection. A normal passive range of motion is a prerequisite.

In the presence of fixed soft tissue or bony deformity, concomitant muscle lengthening, with or without osteotomy, may be required to restore motion and alignment.

Options for split tendon transfer include both the tibialis anterior and the tibialis posterior.

Dynamic EMG can help to determine whether one or both muscles are contributing to the deformity.

A split tibialis anterior tendon transfer, with or without concomitant intramuscular lengthening of the tibialis posterior, may be required in a subset of patients with an equinovarus deformity.

Several techniques have been described for split tibialis posterior transfer.

The most common involves transferring the split tendon (posterior to the tibia and fibula) to the peroneus brevis, either at its insertion or just behind the lateral malleolus. This approach focuses on balancing inversion–eversion but does not address dorsiflexion weakness.

An alternative technique, which may be considered when there is inadequate active dorsiflexion, involves anterior transfer of the split tendon through the interosseous membrane to the peroneus brevis or the lateral cuneiform.

Biomechanical investigations using cadaveric specimens have studied the technical aspects of the split tendon transfer.

Moran et al found that all routing variations reduce the ability of the tibialis posterior to invert the hindfoot, that...
In the technique described by Kaufer, the split tendon is routed behind the tibia and fibula (A) and inserted into the peroneus brevis tendon (B). C. Alternatively, the split tendon can be woven into the peroneus brevis just behind the lateral malleolus. This approach is easier and works as well when the tendon is not long enough.

In the technique described by Muller et al, the split tendon is passed through the interosseous membrane (A) and through a subcutaneous tunnel to insert into the peroneus brevis tendon (B). C. Saji et al transferred the split tendon through the interosseous membrane into the lateral cuneiform.
there was no difference between attaching the tendon proximally or distally into the peroneus brevis, and that transfer through the interosseous membrane reduced the ability to plantarflex the foot. Calculation of muscle moment arms across the subtalar joint suggested that adequate results could be achieved over a wide range of tensioning.

- Other procedures are commonly performed in concert with a split tibialis posterior tendon transfer.
  - Lengthening of the tendo Achilles (gastrocnemius with or without the soleus) is required in most cases of spastic equinovarus deformity. Depending on the degree of myostatic contracture, this can be achieved with either a recession technique (Vulpius, Baker) or a tendinous lengthening (open Z-plasty, percutaneous or open sliding lengthening).
  - Fixed varus deformity of the hindfoot requires a calcaneal osteotomy, either a lateral closing wedge osteotomy (Dwyer) or a sliding lateral displacement osteotomy of the calcaneus. Options for fixation include a staple, a Steinmann pin, or a screw.
  - Older patients with a severe fixed equinovarus deformity may require a triple arthrodesis.
  - A subset of patients may also have tibial torsion of a degree that warrants surgery. Consideration should be given to staging the procedures, as one study suggested that tibial derotational osteotomy should not be performed at the time of tendon transfer because of the increased risk of failure of the tendon transfer.

### Preoperative Planning
- The indications for surgery are based on the physical examination, with or without an instrumented motion analysis study.
- An examination under anesthesia (eliminates spasticity) is performed to assess the range of motion and helps to finalize the surgical plan with respect to the type of soft tissue lengthening procedure.
- The findings will solidify the operative plan with respect to the need for muscle lengthening, the technique employed for lengthening (Z-lengthening versus recession), and whether any supplementary bony procedures are required.

### Positioning
- The patient is placed supine.

### Approach
- Either three or four incisions are employed for split tibialis posterior tendon transfer.
- The tendon must be released from its insertion, tunneled either anteriorly (through the interosseous membrane) or posteriorly behind the tibia and fibula, and then attached to either the peroneus brevis or lateral cuneiform.

### SPLIT TIBIALIS TENDON TRANSFER TO PERONEUS BREVIS (AFTER KAUFER)

- A longitudinal incision is made over the insertion of the tibialis posterior on the navicular, and the sheath is opened (TECH FIG 1A).
  - The plantar half of the tendon is released, and the tendon is split longitudinally (TECH FIG 1B,C).
- A second incision is made just posterior to the medial malleolus, extending proximally for 4 cm (TECH FIG 1D,E).
  - The sheath of the tibialis posterior is split longitudinally, and the free end of the tendon is delivered into this wound.
  - The longitudinal split in the tendon is extended proximally to the musculotendinous junction.
- The third longitudinal incision is made about 2 cm proximal to the tip of the lateral malleolus, and extends proximally (TECH FIG 1F,G).
  - The peroneal tendon sheath is incised longitudinally.
  - The split tendon is then passed posterior to the tibia and fibula, and anterior to the neurovascular bundle, into the third incision. The split tibialis posterior tendon can be sutured into the peroneus brevis tendon at this level (see Fig 1C) or can be transferred distally, which requires a fourth incision.
- The fourth longitudinal incision is made distal to the lateral malleolus, overlying the insertion of the peroneus brevis into the fifth metatarsal base (TECH FIG 1H).
A second incision is made just posterior to the medial border of the tibia, proximal to the medial malleolus. The fascia is divided longitudinally, and the tibialis posterior muscle is identified. The suture ends are delivered from distal to proximal through the tendon sheath, and the split tendon is brought out from the second incision. A short longitudinal incision is then made over the lateral side of the leg, posterior to the fibula, across from the medial incision. The split tendon is then passed from medial to lateral along the posterior border of the tibia and the fibula, anterior to the neurovascular bundle. The tendon is delivered through the lateral wound. The fourth incision is distal, and just behind the fibular malleolus. The peroneal sheath is incised longitudinally. The split tendon is brought through the sheath from the more proximal incision through this distal incision. The tibialis posterior tendon is then woven through small longitudinal splits in the peroneus brevis and anchored with nonabsorbable suture.

- The split tibialis posterior tendon is then passed through the sheath, along the peroneus brevis, into the distal incision (TECH FIG 1I).
- The tendon is woven through the peroneus brevis and secured with nonabsorbable sutures (TECH FIG 1J,K).
- The foot is held in a neutral position.
- A long-leg cast with the knee extended and the foot at neutral (weight bearing as tolerated) is worn for 4 weeks, and then a short-leg cast is worn for 4 additional weeks.
- No bracing is required if the patient is able to actively dorsiflex the foot to neutral. If not, an ankle–foot orthosis is recommended.

A medial approach extends from 5 cm proximal to the medial malleolus to the insertion of the tibialis posterior tendon on the navicular.

- The anterior (dorsal) half of the tendon is released and split up to the musculotendinous junction, preserving the retinaculum.
- A 2-cm incision is made anteriorly, and a window is made in the interosseous membrane just proximal to the syndesmotic ligament.
- The split tendon is passed anteriorly through the interosseous membrane.
A 2-cm incision is made over the lateral cuneiform, and the split tendon is delivered subcutaneously and then passed through a drill hole in the lateral cuneiform. The tendon is secured over a button on the plantar surface of the foot, with the foot held in a neutral position.

The patient is placed in a below-knee cast with the foot in slight valgus and neutral dorsiflexion–plantarflexion. Weight bearing is allowed after 3 weeks, and a brace is worn for 6 to 12 months.

POSTOPERATIVE CARE

- A longitudinal incision is made at the insertion of the tibialis posterior, and the plantar half of the tendon is released from the navicular. The muscle is split longitudinally as described previously.
- A second incision is made proximally, and the tendon is delivered through this incision and split up to the musculotendinous junction.
- The third incision is made anteriorly, and the tendon is delivered through a window in the interosseous membrane (just above the anterior inferior syndesmotic ligament).

The fourth incision is made over the distal insertion of the peroneus brevis tendon, and the tibialis posterior is passed through a subcutaneous tunnel and woven into the distal peroneus brevis with nonabsorbable suture.

A long-leg cast is used for 3 weeks and then a short-leg cast (weight bearing as tolerated) for an additional 3 weeks.

COMPPLICATIONS

- While immediate complications are uncommon (wound infection, pull-out of the transferred tendon, undercorrection or overcorrection), late complications are more common and relate to the effects of many variables in a growing child with spasticity and persistent neuromuscular imbalance.
- Recurrent deformity results from persistent muscle imbalance, pull-out of the tibialis posterior from the peroneus brevis, insufficient tension when suturing the tibialis posterior tendon, or other variables associated with growth.
- Overcorrection into valgus is most common in younger children and in patients treated by concurrent tibial derotational osteotomy.

REFERENCES

DEFINITION
- Adolescent bunion is a complex deformity consisting of medial deviation of the first metatarsal (metatarsus primus varus), lateral deviation of the great toe through the first metatarsophalangeal joint (hallux valgus), and enlarged medial eminence of the distal first metatarsal.
- Other findings include contracted lateral and lax medial soft tissues of the first metatarsophalangeal joint, lateral subluxation of the sesamoids, pronation of the great toe, and plantar subluxation of the abductor hallucis muscle.

ANATOMY
- Metatarsus primus varus
- Obliquity of the medial cuneiform–first metatarsal joint
- Medial prominence of the first metatarsal head
- Valgus angulation through the first metatarsophalangeal joint
- Minimal or no deformity through the first interphalangeal joint
- Lateral translation of sesamoids
- Plantar-lateral positioning of the abductor hallucis with unopposed pull of the adductor hallucis muscle
- Lateral subluxation of the extensor hallucis longus and flexor hallucis longus tendons
- Pronation (internal rotation) of the first toe
- Differs from an adult bunion:
  - Physis of the first metatarsal and proximal phalanx are located proximally (this limits ability to perform proximal osteotomies in skeletally immature patients).
  - The first metatarsophalangeal joint does not have osteoarthrosis.
  - The medial eminence is less prominent in adolescent bunions than in adult bunions.

PATHOGENESIS
- Multiple theories exist; it is difficult to differentiate primary findings from secondary ones.
- Extrinsic and intrinsic factors contribute to formation of adolescent bunions.
- Intrinsic
  - Metatarsus primus varus
  - Obliquity of the medial cuneiform–first metatarsal joint
  - Long first metatarsal
  - Ligamentous laxity
  - Heelcord contracture causes foot pronation, which in turn places a valgus force on the hallux while walking
- Extrinsic
  - Shoe wear, particularly those with a narrow toe and elevated heel

NATURAL HISTORY
- Natural history is believed to be favorable. Most patients with adolescent bunions can be treated nonoperatively.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients typically present in late childhood or adolescence.
- Complaints about appearance of foot.
- Complaints of pain over the medial exostosis or about the first metatarsophalangeal joint.
- Pain is exacerbated by shoe wear.
- Complaints about finding shoes that are comfortable.
- Physical examination
  - Areas of tenderness: first metatarsophalangeal joint, medial prominence
  - Alignment when standing and walking
  - Mobility of first metatarsophalangeal joint
  - Skin condition: the clinician should search for calluses, areas of irritation
  - Foot and ankle range of motion
  - Careful neurologic examination

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Standing anteroposterior (AP), lateral, and oblique radiographs should be obtained if surgical correction is being contemplated.
- Measurements on the AP radiograph (FIG 1)
  - Intermetatarsal (IM) angle: normal is 9 degrees or less
  - IM angle usually is 12 to 18 degrees in adolescent bunion.

FIG 1 • Measurements made on the AP radiograph.
Expose the medial first metatarsophalangeal joint.

Make a distally based Y-shaped incision in the capsule and periosteum. The stem of the Y is over the metatarsal, while the upper portion of the Y is formed distally.

The joint and medial eminence are then exposed.

A medial release of the first metatarsophalangeal joint is performed. Leave the lateral portion of the joint intact to avoid disrupting the blood supply to the head of the first metatarsal.

The first cut involves removing the prominent medial eminence with an osteotome, starting distally at the sagittal groove (groove of Clark).

The second cut is made at the distal metaphyseal–diaphyseal junction of the first metatarsal. This should be perpendicular to the shaft of the first metatarsal and extend two-thirds the width of the shaft of the first metatarsal (TECH FIG 1A).

The third, proximal cut is made about 2 to 3 mm proximal to the first cut, and is created completely across the first metatarsal. The cut is oriented perpendicular to the shaft of the second metatarsal when viewed from the dorsum of the foot and is angled (when viewed from the medial aspect of the first metatarsal) to create a small plantar-based wedge (TECH FIG 1B). This ensures that the distal fragment does not dorsiflex during reduction of the osteotomy.

The interposed bone is removed.

The osteotomy is reduced and pinned with two smooth 0.062-inch Kirschner wires (TECH FIG 1C).

The prominence of the distal portion of the metatarsal shaft is smoothed off with a rongeur, and a capsulorrhaphy is performed with absorbable sutures.

Sterile dressings are applied and the toe is splinted in neutral to slight plantarflexion. A short-leg cast is usually applied over the dressing for additional protection.
POSTOPERATIVE CARE
- The toe is splinted in slight flexion.
- The dressing is covered with a cast.
- Weight bearing is allowed as tolerated.
- Pins are removed in 6 weeks.

OUTCOMES
- Most studies report 65% to 85% good to excellent results with the Mitchell osteotomy.
- The modified Mitchell osteotomy (described above) produces 81% satisfactory results, with no cases of malunion, nonunion, avascular necrosis of the first metatarsal head, infection, or transfer metatarsalgia.
- Sixty percent good to excellent results are reported in younger patients.

COMPLICATIONS
- Infection
- Neurovascular injury
- Inadequate fixation of the osteotomy
- Malunion or nonunion of the osteotomy
- Avascular necrosis of the first metatarsal head
- Transfer metatarsalgia
- Recurrence
- Stiffness of the first metatarsophalangeal joint
- Hallux varus (overcorrection)
- Pronation
- Pain

REFERENCES
DEFINITION

- Overlapping fifth toe is a congenital condition where the fifth toe is rotated and overrides the fourth toe.
- It is frequently bilateral.
- Males are affected as frequently as females.

ANATOMY

- There are six main components:
  - The fifth toe may be smaller than normal.
  - The fifth toe is adducted toward the fourth toe.
  - The fifth metatarsophalangeal joint has a dorsiflexion contracture.
  - The phalanges of the fifth toe are rotated laterally.
  - The fifth extensor digitorum longus tendon is shortened.
  - The fifth metatarsophalangeal joint is dislocated dorsally.

PATHOGENESIS

- The exact pathogenesis is unknown, but the condition is believed to be secondary to a congenital contracture of the fifth extensor digitorum longus tendon.

NATURAL HISTORY

- This condition rarely causes pain or difficulty in shoe wear in children less than 10 years of age.
- In older children and adolescents there will be painful dorsal callosities about 50% of the time.
- There may also be difficulty in finding shoes that fit appropriately in older children and adolescents.
- Parents are frequently concerned about the cosmetic appearance of the foot.

PATIENT HISTORY AND PHYSICAL FINDINGS

- The fifth toe will be dorsiflexed, adducted, and laterally rotated. It will not be passively correctable into a neutral position.
- A careful neurovascular examination should be performed and documented.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain anteroposterior (AP), lateral, and oblique radiographs may be obtained and will demonstrate a dorsolaterally subluxated fifth metatarsophalangeal joint.

NONOPERATIVE MANAGEMENT

- Conservative treatment (eg, stretching, splinting, taping) is ineffective in the treatment of this condition.

SURGICAL MANAGEMENT

- Surgery is indicated when nonoperative treatment fails, such as failure to find comfortable shoes, or when there is intractable pain from shoes.

Positioning

- The patient is supine, preferably with a bolster beneath the ipsilateral hemipelvis to make the lateral foot more accessible.
- A tourniquet should be used during the procedure.
BUTLER PROCEDURE FOR OVERLAPPING FIFTH TOE

- A dorsal racquet incision is made about the toe with a second handle to the racquet added on the plantar aspect of the toe (TECH FIG 1A).
- The plantar handle should be slightly longer than the dorsal handle and directed slightly laterally.
- The skin flaps are elevated and the tight extensor tendon is exposed.
- Care should be taken to preserve the neurovascular bundles (TECH FIG 1B).
- The extensor tendon is divided, and a dorsomedial release of the fifth metatarsophalangeal joint is performed. If needed, the plantar aspect of the fifth metatarsophalangeal joint may be dissected off the metatarsal head and divided to increase joint mobility (TECH FIG 1C).
- The toe should freely move plantarward and laterally into its corrected position (TECH FIG 1D).
- There should be no tension on the toe, and the toe should rest within the plantar handle of the racquet incision.
- Interrupted sutures are then used to hold the toe reduced in place (TECH FIG 1E).
- A cast or hard-soled shoe can be used postoperatively.

PEARLS AND PITFALLS

POSTOPERATIVE CARE

- Postoperative care includes sterile dressings, and allowing mobilization and weight bearing as tolerated.

OUTCOMES

- This procedure has a high patient satisfaction rate (about 90%) in various studies.
- Black et al\(^1\) reported 94% good or excellent results.

COMPLICATIONS

- Incomplete correction
- Neurovascular compromise
- Scar contracture
- Infection

REFERENCES

DEFINITION
- A cavus foot deformity in children develops from muscle imbalance that leads to forefoot pronation in relation to the hindfoot. When well established, it is readily recognizable by an abnormally high medial arch that persists with weight bearing (FIG 1).
- Commonly a result of hereditary sensory motor neuropathy (HSMN), it is frequently difficult to determine the underlying cause.

ANATOMY
- The plantar fascia is an extensive fibrous structure that spans the foot between the medial aspect of the calcaneal tuberosity and the transverse metatarsal ligaments at the metatarsal heads (FIG 2). It stabilizes the arch of the foot and protects the underlying neurovascular structures from injury.
- During the gait cycle, the plantar fascia assists in the dynamic changes of the arch.
  - At heel strike there is forefoot supination and heel inversion, while eccentric contraction of the quadriceps muscles absorbs much of the energy.
  - During mid-stance, there is unlocking of the midtarsal joints with hindfoot pronation and internal tibia rotation.
  - At toe off the plantar fascia helps lock the midtarsal joints to assist the foot to be a rigid lever for forward propulsion.
- This is termed the windlass effect, when passive dorsiflexion at the metatarsophalangeal joints tightens the plantar fascia, leading to elevation of the medial arch and tarsal joint stability (FIG 3).

PATHOGENESIS
- In progressive conditions such as HSMN, there is muscle imbalance with weakness of the intrinsic, tibialis anterior, and peroneus brevis muscles. This can lead to a relative overpull of the peroneus longus and posterior tibialis muscles.
- Clinical muscle testing shows that although both peroneal muscles are weak, the larger peroneus longus muscle retains relatively more strength. Differential peroneal nerve compression at the proximal fibula is postulated to cause relative sparing of the peroneus longus innervation.\(^6\)
- CT imaging studies in Charcot-Marie-Tooth disease, a major category of HSMN, showed early foot intrinsic muscle atrophy with sparing of the abductor hallucis and involvement of the peroneus brevis, peroneus longus, and flexor hallucis longus muscles.\(^11\)
- MRI studies have shown dominance in the size of the peroneus longus muscle versus the tibialis anterior.\(^14\)
- The muscle imbalance and intrinsic muscle weakness lead to an unopposed extensor digitorum longus, hyperextension of the lesser toe metatarsophalangeal joints, and phalangeal joint flexion by the long and short toe flexors.
- There is an exaggeration of the windlass effect with claw toe deformities.
- The first metatarsal becomes even more plantarflexed by the action of the peroneus longus and with time becomes fixed in this position.
- The plantar aspect of the foot assumes a tripod position, resulting in hindfoot varus (FIG 4).
- The cavus foot remains a rigid lever throughout stance phase, leading to increased stress and lack of shock absorption, pain, and callosities.
Cavus foot deformity involves either a dorsiflexion deformity of the calcaneus or a forefoot plantarflexion deformity.

The most common cause of progressive bilateral cavus foot deformity is HSMN. HSMN is a group of progressive peripheral nerve diseases and has a heterogeneous genetic classification.

Charcot-Marie-Tooth disease involves types I and II HSMN, with HSMN IA the most common type, seen in 60% of HSMN.

HSMN type I has myelin degeneration, type II is the axonal degeneration form, and type III (Dejerine-Sottas disease) is more severe and presents in infancy.

There are more than 17 different genetic loci determined for CMT.

The prognosis for these progressive conditions is less favorable than for the nonprogressive disorders.

The natural history of HSMN is related to the underlying type.

Progression of muscle involvement begins initially in the intrinsic muscles, followed by the anterior compartment, the peroneal muscles, and then the posterior muscles.

The foot can assume a cavovarus, calcaneocavus deformity or even a valgus deformity and may have more unilateral severity (HSMN type III).

Associated hip dysplasia may be asymptomatic or may present with symptoms. Acetabular dysplasia may be the first indicator of HSMN.

In progressive conditions that are left untreated, a flexible and correctable foot may become rigid with structural bony changes. This can lead to inability to participate in athletics and pain and difficulty with shoe wear and normal walking. Treatment is recommended when the foot is still flexible.

Unilateral cavus foot can have a number of causes. The idiopathic variety may be progressive, with an unpredictable natural history.

**NATURAL HISTORY**

- Cavus foot is rarely present at birth, but develops with time.
- The natural history depends on the underlying diagnosis. The underlying cause affects the outcome, so determination of cause is essential. An underlying diagnosis can be found in the brain, spinal cord, peripheral nerves, or the foot itself.
- Cavus foot deformity can be either progressive or nonprogressive.

**FIG 3** Windlass effect. The foot is an arch. If the plantar tissues tighten and become shorter, the fixed length of the arch forces it to become taller.

**FIG 4** Tripod effect. Weight bearing is shared between the heel and medial and lateral columns of the forefoot. If the medial column is in plantarflexion, the heel is forced into varus with weight bearing.
Patients with nonprogressive conditions, as seen in cerebral palsy or spinal cord disorders, may fare better but still can have long-term problems with athletics, metatarsalgia, plantar fasciitis, and iliotibial band syndrome.\(^9\)

Calcaneocavus deformity is often seen with nonprogressive conditions such as spina bifida or clubfoot deformity with an overlengthened heel cord. Problems include heel pain or heel pad ulceration if sensation is deficient, and weak or no push-off or crouch gait if not braced.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- The physical examination is used to determine the underlying diagnosis and to determine characteristics of the cavus foot deformity that would indicate surgical correction is needed.
- Physical examination should include observation of the spine and its range of motion. Skin changes, scoliosis, or kyphosis may represent an underlying spinal cord abnormality.
- The upper extremities are evaluated for intrinsic muscle wasting and weakness. Atrophy or weakness in the hand suggests HSMN.
- The clinician evaluates hip range of motion and looks for Trendelenburg gait. Bilateral hip dysplasia newly diagnosed in a teenager is highly suggestive of HSMN.
- Lower extremities are evaluated for size, muscle strength, and firmness and tenderness along the course of major nerves. Bilateral calf atrophy is seen with spina bifida and may be present in severe HSMN. Unilateral atrophy may be seen with diastatomyelia, tethered spinal cord, or split cord malformation.
- A neural examination is performed. Patients with HSMN may have decreased sensation to light touch, position sense, or vibration. There may be obvious weakness of the anterior tibialis muscle, preventing ability to heel walk. Deep tendon reflexes may be decreased or absent in HSMN and Friedrich ataxia.
- The foot is examined for deformity (cavus, cavovarus, or calcaneocavus). Bilateral deformity is typical for HSMN. Unilateral deformity may be present with a structural abnormality. The clinician locates the apex of the midfoot deformity and determines whether the foot is rigid or flexible. Hindfoot is rarely in equinus.
- The Coleman block test is performed. If hindfoot varus corrects to neutral position, then the hindfoot is flexible and the medial forefoot is the source of hindfoot varus.
- The toes are examined for any deformities. Cavus foot may not have associated toe abnormality. Rigid claw toe abnormality requires surgical treatment.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

- Bilateral standing anteroposterior (AP) and lateral radiographs are standard.
- On the lateral weight-bearing radiograph the clinician should determine the calcaneal pitch; greater than 30 degrees indicates chronic gastrocnemius-soleus weakness (**FIG 5A**).
- The Meary angle, the angle between the shaft of the first metatarsal and the axis of the talus, is normally 0 degrees (**FIG 5A**).
- Ankle equinus, forefoot equinus, the amount of cavus, and the apex of the midfoot deformity are determined.
- With the foot positioned for the Coleman block test, a lateral radiograph of the foot can document the degree of hindfoot correction.\(^1\)
- In the patient with known or possible HSMN, a standing AP pelvis view is obtained to document the presence of hip dysplasia.\(^15\)
- Standing full-length posteroanterior and lateral spine radiographs are obtained when a spinal abnormality is suspected or if the underlying diagnosis is in question.

**FIG 5 • A.** A 15-year-old boy with hereditary sensory motor neuropathy type 1A with severe bilateral cavus foot deformity. Lateral standing radiograph of right foot. The Meary angle, measured between the axis of the talus and the first metatarsal, is 25 degrees, but it should be 0 degrees. The calcaneal pitch angle, measured between the horizontal and the plantar aspect of the calcaneus, is 26 degrees but should be less than 20 degrees. **B.** A 5-year-old girl with 28-degree right thoracic scoliosis. MRI T1-weighted sagittal view of large cervical thoracic syrinx with Chiari I malformation at foramen magnum. (**continued**)
MRI of the entire brainstem and cervical, thoracic, and lumbar spine is performed when a spinal cord tumor, syrinx, tethered cord, or Chiari I malformation is of concern (FIG 5B,C).

Nerve conduction and electromyelographic (EMG) studies may be done to evaluate for HMSN. In HMSN type I, motor nerve conduction is markedly slowed. In HMSN type II, there is near-normal motor nerve conduction but EMG evidence of denervation. Molecular DNA testing of peripheral blood may be used for diagnosing HSMN; therefore, sural nerve biopsy is generally not necessary.

DIFFERENTIAL DIAGNOSIS

- Hemiplegic cerebral palsy
- Spastic diplegic cerebral palsy with calcaneocavus foot deformity if the Achilles tendon has been overlengthened
- Friedrich ataxia
- Myelodysplasia
- Chiari I malformation with syringomyelia and scoliosis
- Diastatomegaly and split cord malformation
- Poliomyelitis
- Spinal cord tumors
- Guillain-Barré syndrome
- Peripheral nerves: HSMN types I and II
- Sciatic nerve injury
- Peripheral nerve tumor
- Silent compartment syndrome after tibia or foot fracture
- Residual deformity of clubfoot
- Idiopathic
- Subtalar tarsal coalition (rare)
- Severe limb-length discrepancy leading to a fixed equinus gait

NONOPERATIVE MANAGEMENT

Nonoperative management is appropriate for mild or nonprogressive deformity.

- Inserts that support the lateral forefoot and eliminate hindfoot inversion may be helpful.
- Gel heel cups and replacing worn athletic shoes assist the stiff foot in energy absorption.
- Extra-depth shoes and orthotics that unload pressure points may help in more advanced cases.

SURGICAL MANAGEMENT

- Surgical treatment is necessary for more severe nonprogressive cases or for progressive cases. The functional goal is to correct the cavus deformity and to obtain a mobile, plantigrade, and well-balanced foot while avoiding common pitfalls. Treatment is best performed when the foot is still flexible. Staged procedures, correcting deformity first and balancing muscles at a later stage, may be safer for the foot.

Specific principles for surgical decision making include the following:

- Surgical management is usually needed when there is an identified functional problem or progression of the deformity. For progressive cavus deformity, it is better to use simple procedures early.
- Plantar fascia release is the initial procedure of choice in young children with nonprogressive deformity. We prefer to do this through a medial plantar incision with postoperative serial corrective casting used to gain further correction. Plantar fascia release is generally done with other procedures.
- The surgeon can correct any underlying muscle imbalance with tendon transfers or lengthening or by bony correction of the lever arm that the muscles work through.

- In a more rigid deformity, a forefoot osteotomy is used to correct the pronated medial forefoot.

- The goal is to correct the fixed deformity while preserving joint mobility. The site of the osteotomy is determined by the location of the deformity apex. The most common are first metatarsal dorsal closing, medial cuneiform plantar opening, and midfoot wedge osteotomies.

- For marked and rigid forefoot equinus (FIG 6), a more extensive midfoot osteotomy is used, which is typically needed during the patient’s second decade.\(^1^7\)

- Calcaneal osteotomy is used if the Coleman block test indicates a fixed heel varus. We recommend a slide osteotomy through a lateral approach, although a lateral closing wedge alone or combined with the slide may also be used for more correction. Tendon transfers are frequently required to achieve a balanced foot. These may involve a transfer of the relatively strong posterior tibialis tendon to the dorsum of the foot,\(^1^\) a Jones procedure in which the extensor hallucis tendon is transferred to the neck of the first metatarsal with fusion of the great toe interphalangeal joint, a split or complete anterior tibialis tendon transfer if

**FIG 5 • (continued)** C. MRI T1-weighted axial view showing large central cord syrinx.

**FIG 6 •** An 18-year-old girl with hereditary sensory motor neuropathy type 1A with marked cavus and fixed midfoot deformity and shortening. Owing to her age and the degree of rigid deformity, a midfoot osteotomy is required.
the muscle has preserved strength, or a transfer of the peroneus longus to the peroneus brevis.\(^{18}\)
- Calcaneal cavus deformity may need a posterior sliding calcaneal osteotomy to increase the calcaneal lever arm. We prefer this to be a crescent-shaped cut. A plantar fascia release facilitates posterior sliding of the distal fragment.
- Triple arthrodesis is used as a salvage procedure for rigid hindfoot deformity. We are reluctant to recommend this for a foot with sensory deficit since the long-term outcome when this procedure is used is poor.\(^{16}\) With a triple arthrodesis, tendon transfers may still be necessary to maintain a balanced foot.

**Preoperative Planning**
- Intraoperative epidural anesthesia may be continued in the postoperative period.
- Preoperative antibiotics are given.
- A tourniquet allows optimal visualization of the operative site.
- In patients with HSMN, the surgeon must be very careful about tourniquet use, since the sciatic and femoral nerves in the thigh are very sensitive to the pressure and time effects of the tourniquet. We recommend the minimal pressure needed and less than 1 hour of inflation time.

**Positioning**
- The patient is positioned supine on a radiolucent imaging table.

**Approach**
- A combination of surgical procedures may be needed to fully correct the foot deformity.
- For most deformities, an extensive plantar release is used.
- As the extensor hallucis longus muscle function may be spared in HSMN, the Jones procedure is useful for the child with a plantarflexed medial column and dynamic great toe hyperextension during swing phase. It is generally combined with a medial or midfoot osteotomy.
- For more extensive and rigid deformity, an osteotomy may be needed. A younger patient may require only an osteotomy of the proximal first metatarsal or first cuneiform. A midfoot wedge osteotomy is useful for the rigid midfoot deformity in an adolescent or young adult when the midfoot does not sufficiently correct after the plantar fascia release. If the lateral and medial aspects of the midfoot are in equinus, an osteotomy across the entire midfoot will more reliably correct the deformity than a medial column osteotomy.
- The lateral calcaneal slide osteotomy is used to correct fixed hindfoot varus that does not correct with the Coleman block test.
- Advantages include use of a simple single cut with control of the amount of correction needed.
- The posterior slide calcaneal osteotomy is useful in the calcaneocavus foot with a high calcaneal pitch angle.
- Incisions should be longitudinal and placed over the areas of relevant pathology (FIG 7).
- A cavus foot is short and will be lengthened in the course of treatment. It may be safer to obtain some of the correction with postoperative corrective casts rather than doing all of the correction at the initial surgery.

**PLANTAR RELEASE**
- A longitudinal incision is made medially over the plantar fascia. Sharp knife dissection is used through the skin and subcutaneous fat (TECH FIG 1A).
- The abductor hallucis is the first structure identified and is released off its deep fascia (TECH FIG 1B).
- The fascia deep to the abductor hallucis is next exposed. The posterior tibial nerve and artery are identified proximally and followed distally by releasing the overlying fascia. Note the division of the posterior tibial nerve into its plantar medial and lateral branches.
- Posterior to the neurovascular bundle the plantar fascia is exposed as it attaches to the medial tubercle of the calcaneus.
- The flexor digitorum brevis, quadratus plantae, and abductor digiti quinti muscles are released at their proximal origins with Mayo scissors.
- Capsulotomies of the medial talonavicular and subtalar joints may be needed if superficial release is not adequate to achieve correction.\(^{2}\)
- Severe cases may need posterior tibialis tendon lengthening or transfer.
- The incision is loosely closed with interrupted sutures. By widely spacing the sutures, blood can drain and not cause excessive postoperative pressure.
- In severe cases serial casting may be necessary after the release.
A plantar medial release should also be performed if an osteotomy is required. A stiff forefoot, an older patient, or painful forefoot calluses indicate the need for an osteotomy. Depending on the apex of the deformity, the osteotomy can be performed on the medial cuneiform or the first metatarsal. In a younger child, it may be safer to avoid the proximal metatarsal physis and perform a medial cuneiform osteotomy. The osteotomy can be performed either as a first metatarsal dorsal-based closing wedge osteotomy or as a medial cuneiform plantar-based open wedge. The first metatarsal dorsal closing wedge osteotomy does not require a bone graft, has one bony surface to heal, and can be held closed with a single screw. However, it may shorten the metatarsal slightly. The first cuneiform plantar open wedge osteotomy requires only a single cut, the amount of correction can be fine-tuned after the bone has been cut, and it does not shorten the foot, but a bone graft is required to hold it open, typically an allograft. For a proximal, dorsal-based oblique closing wedge first metatarsal osteotomy, a longitudinal incision is made directly over the proximal metatarsal; be careful to protect the dorsal digital nerve (TECH FIG 2A,B). Subperiosteal dissection of the proximal metatarsal is used; be careful to leave the plantar periosteum and soft tissue intact.

Two small-diameter Steinmann pins are drilled at the site of the bone cuts, converging at the plantar apex. The apex of the correction is quite proximal and plantar. A bony and soft tissue posterior hinge is left intact so that the osteotomy is an incomplete closing wedge. A small oscillating saw is used to make the bone cuts. The wires are used to guide the cuts toward the plantar apex. A small osteotome and pituitary rongeur may be used to remove some of the bone at the apex.

MEDIAL COLUMN OSTEOTOMY

- A plantar medial release should also be performed if an osteotomy is required.
- A stiff forefoot, an older patient, or painful forefoot calluses indicate the need for an osteotomy.
- Depending on the apex of the deformity, the osteotomy can be performed on the medial cuneiform or the first metatarsal. In a younger child, it may be safer to avoid the proximal metatarsal physis and perform a medial cuneiform osteotomy.
- The osteotomy can be performed either as a first metatarsal dorsal-based closing wedge osteotomy or as a medial cuneiform plantar-based open wedge.
- The first metatarsal dorsal closing wedge osteotomy does not require a bone graft, has one bony surface to heal, and can be held closed with a single screw. However, it may shorten the metatarsal slightly.
- The first cuneiform plantar open wedge osteotomy requires only a single cut, the amount of correction can be fine-tuned after the bone has been cut, and it does not shorten the foot, but a bone graft is required to hold it open, typically an allograft.
- For a proximal, dorsal-based oblique closing wedge first metatarsal osteotomy, a longitudinal incision is made directly over the proximal metatarsal; be careful to protect the dorsal digital nerve (TECH FIG 2A,B).
- Subperiosteal dissection of the proximal metatarsal is used; be careful to leave the plantar periosteum and soft tissue intact.

A proximal incomplete dorsal-based closing wedge osteotomy of proximal metatarsal. The plantar aspect of the metatarsal and soft tissues are left intact to act as a hinge to allow closure of the osteotomy. Steinmann pins are placed to accurately guide the bony cuts. (continued)
Interphalangeal Joint Fusion

- Through the transverse incision over the IP joint, the incision is carried down to the extensor hallucis tendon.
- The tendon is transected at the level of the IP joint and the IP joint capsule is incised transversely.
- Continue with the no. 15 blade to expose the articular distal aspect of the proximal phalanx.
- A rongeur is used to remove the articular cartilage and some of the subchondral cortical bone on both sides of the IP joint. Only a minimal amount of bone is removed.
- A cannulated 4.0-mm screw is used for fixation. This is placed by retrograde insertion of a guidewire through the center of the distal phalanx, exiting distally just plantar to the nail.
- The IP joint is then reduced in a neutral position and the screw is inserted; be careful to provide compression at the IP joint.
- Proper length places the tip of the screw into the proximal aspect of the proximal phalanx.

When sufficient bone has been removed from the apex, the cut ends can be slowly closed together, while maintaining integrity of the bony hinge. A wire, screw, or dorsal plate can be used to secure the corrected osteotomy.

In a younger child with an open metatarsal physis or when the deformity apex is at the medial cuneiform, the opening wedge osteotomy can be performed at this level (TECH FIG 2C,D).
Transfer of the Extensor Hallucis Tendon to the Metatarsal Neck

- A longitudinal skin incision is made over the distal first metatarsal.
- The extensor hallucis tendon is identified and isolated distally until its cut end can be pulled into the incision.
- A 0 suture whipstitch is placed into the distal tendon.
- Subperiosteal exposure of the distal metatarsal allows a transverse drill hole to be made in the metatarsal neck.
  - The drill diameter is roughly the diameter of the extensor hallucis longus tendon.
  - A wire or suture passer aids passage of the extensor hallucis longus tendon through the hole.
- After the medial column or midfoot osteotomy is secured, the end of the extensor hallucis longus tendon is secured to itself (TECH FIG 4).

**TECH FIG 4** • After denuding the interphalangeal joint articular cartilage, a 4.0-mm screw transfixes this joint. A whipstitch is placed into the cut end of the extensor hallucis longus tendon (inset) and the tendon is passed through a transverse drill hole and sutured to itself.

MIDFOOT OSTEOTOMY

- The osteotomy is placed at the apex of the deformity, which should be proximal to any plantar calluses (TECH FIG 5A,B).
  - Too distal placement results in a rocker-bottom residual deformity.
  - If the deformity is severe, a triple arthrodesis may be needed to bring the forefoot into a plantigrade position.
- Muscle balancing procedures will still be required, since the foot will further deform with time if imbalance remains.
  - Several types of osteotomies have been described.  
  6,7,17
- We recommend a simple procedure that uses a truncated wedge placed at the apex of the deformity.
  - Once cut, the distal fragment may be laterally rotated to compensate for excessive medial column flexion.
- A long single dorsomedial skin incision is used at the apex of the deformity.
  - It is more effective to place the osteotomy proximally so that correction is achieved at the level of the deformity; it is generally at the navicular cuneiform joint.
- The Hohmann retractors are placed dorsal and plantar, with the entire midfoot exposed (TECH FIG 5C).

**TECH FIG 5** • A,B. Midfoot osteotomy is centered at the apex of the deformity, typically through the naviculocuneiform joint. Rotation can be added to decrease the excessive amount of medial column plantarflexion. (continued)
Lateral Calcaneal Slide Osteotomy

- The incision is placed lateral to the calcaneus, parallel to the peroneal tendons.
- The peroneal tendons are reflected proximally to gain access to the lateral aspect of the calcaneus tubercle.
- A sharp Hohmann retractor is placed just anterior to the Achilles insertion and another is placed plantar and distal.
- Fluoroscopy can be used to check the orientation of the osteotomy by the position of the retractors (TECH FIG 6A).
- A 1-inch osteotome or saw is used to make the osteotomy across the calcaneus to the opposite cortex. A smooth lamina spreader is used to distract the fragments, and the medial cortex can be freed up with a pituitary rongeur and a Cobb elevator.
- The calcaneal tubercle with the heel is then slid medially about 50% of its width. The correct position is for the heel to be underneath and in line with the tibial shaft (TECH FIG 6B). A laterally-based wedge can also be removed if more correction is needed.
- A large threaded Steinmann pin is placed in the sinus tarsi and directed toward the most posterior inferior aspect of the tubercle (TECH FIG 6C).
- The pin is removed in the clinic in 3 weeks. A cast is used for a total of 6 weeks.
**PEARLS AND PITFALLS**

| Failure to diagnose underlying spine condition | A child presenting with a foot problem must always have the spine examined.  
| | A markedly small foot or calf may be a sign of a split cord malformation or diastatomyelia. |
| Failure to diagnose a structural lesion of a major nerve | The clinician must examine the entire lower limbs along the course of major nerves to detect a localized peripheral nerve tumor or site of nerve compression. |
| Failure to diagnose HSMN | Bilateral cavus may be subtle.  
| | The clinician should always ask about a family history of cavus feet or peripheral neuropathy.  
| | Sometimes there is not an established diagnosis of HSMN in the family. In these cases the family members may need to be examined.  
| | The hand and foot intrinsics are examined.  
| | HSMN may initially present as bilateral adolescent hip dysplasia. |
| Missing a diagnosis with a very treatable lesion | Several conditions may cause a cavus foot deformity. Subtalar coalition generally causes a rigid valgus hindfoot deformity but may cause a spastic hindfoot varus (FIG 8). |
| Insufficient surgical procedure | With adolescence, severe cavus deformities often require a more extensive midfoot osteotomy to correct the deformity. |
| Severe idiopathic cavus foot deformity often requires repeat surgical procedures | The family should be warned that further surgical procedures may be necessary with time as the child grows and the deformity changes. |

---

**Posterior Slide Calcaneal Osteotomy**

- A lateral approach to the calcaneus is used, similar to the lateral slide osteotomy.
- Hohmann retractors are placed for protection and orientation.
- An oblique straight cut may be used, but we prefer a curved cut using a Chiari chisel (TECH FIG 7).
- Once cut, the distal calcaneal fragment is slid posterior and transfixed with a threaded Steinmann pin.
- Since the bone may continue to bleed, loose interrupted suture closure and a bulky dressing are used.
- The pin is removed in 3 weeks and the foot is casted for a total of 6 weeks.

**TECH FIG 7** • Crescent-shaped calcaneal osteotomy allows posterior positioning of the calcaneus to improve the lever arm function of the gastrocsoleus muscles and to decrease the point pressure on the heel.
POSTOPERATIVE CARE
- After a plantar release, the foot should be wrapped with soft bulky cotton and casted with minimal external correction.
- At 2 weeks the sutures are removed and gentle correction is obtained. This may require serial casting for up to 6 weeks.
- After a midfoot or forefoot osteotomy, weight bearing is restricted until the osteotomy has healed, generally about 6 weeks.

OUTCOMES
- Long-term outcome studies are very limited for progressive conditions such as HSMN.
- Triple arthrodesis for progressive cavus deformity has a poor long-term outcome. Results are further compromised by technical problems at the time of surgery, as well as from undercorrection and overcorrection.
- Most patients with a progressive cavus deformity and a triple arthrodesis performed as a teenager had significant foot problems by their thirties.16
- Nonprogressive deformities such as spastic cavovarus with equinus can be surgically balanced with acceptable results.
- Progressive deformities may require several surgeries during childhood followed by a triple arthrodesis at maturity. The patient and family should be warned about this possibility.

COMPLICATIONS
- Femoral or sciatic nerve injury from tourniquet. This can occur with excessive pressure or time on the tourniquet or even with minimal time and pressure. The tourniquet time should be under 1 hour, using minimal pressure needed for visualization.
- Plantar medial incision dehiscence if excessive correction is attempted at the time of surgery.
- Pressure sores in patients with HSMN.
- Surgical correction of midfoot deformity distal to the apex may result in a rocker-bottom foot deformity.
- Nonunion of the midfoot osteotomy
- Persistent midfoot cavus if the deformity is too severe for a medial column or midfoot osteotomy.
- Persistent hindfoot varus if deformity is fixed and a calcaneal osteotomy is not performed.

REFERENCES
DEFINITION
- A calcaneonavicular coalition is an abnormal connection between the calcaneus and the navicular.
- This extra connection between the tarsal bones typically limits subtalar motion.
- The major consequence of this condition is a rigid flatfoot that may be painful.

ANATOMY
- The coalition typically occurs between the anterior process of the calcaneus and the most lateral aspect of the navicular (FIG 1).
- The connection may comprise bone, cartilage, or fibrous tissue (bony, cartilaginous, or fibrous coalitions, respectively).

PATHOGENESIS
- The cause of calcaneonavicular coalitions remains unknown.
- It has been hypothesized that coalitions may result from failure of segmentation of the individual tarsal bones during fetal development.1
- Symptoms typically develop in later childhood, usually between 8 and 12 years old, for calcaneonavicular coalitions.5
- It is theorized that the reason for the delayed onset of symptoms, despite presumed presence from birth, is that the coalition ossifies over time, making it more rigid and more likely to limit subtalar motion.5
- The pain from a calcaneonavicular coalition may arise from altered kinematics of the foot due to local limitation of motion. It has also been suggested that a fracture through a previously solid coalition could render it painful.

NATURAL HISTORY
- Many people with calcaneonavicular coalitions are probably pain-free, although they may have a rigid flatfoot, with loss of the longitudinal arch and valgus alignment of the heel.6
- If pain develops in a child with a calcaneonavicular coalition, it usually does so between ages 8 and 12.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Patients present with complaints of foot pain exacerbated by activity, typically localized to the lateral aspect of the foot, just distal to the sinus tarsi, in the region of the anterior process of the calcaneus. They may complain of medial foot and ankle pain or pain at the distal tip of the fibula as well.
- There may be a history of progressive out-toeing and loss of arch height due to an increase in the planovalgus position of the foot.
- Patients may also relate difficulty walking on uneven surfaces, presumably due to decreased subtalar motion.
- The physician should observe the patient’s gait; he or she may walk with an antalgic gait on the affected side (decreased stance phase) and an out-toeing gait.
- The physician should examine the patient’s foot alignment. The heel may be in valgus alignment with the forefoot abducted.
- The physician should examine the rigidity of the patient’s flatfoot. A flexible flatfoot has restoration of the arch upon toe-rise, while a rigid flatfoot has no arch restoration. A rigid flatfoot is a sign of decreased subtalar motion and may indicate a tarsal coalition.
- The physician should palpate over the anterior process of the calcaneus and just distal to the anterior process. Point tenderness is suggestive of a painful calcaneonavicular coalition.

IMAGING AND OTHER DIAGNOSTIC STUDIES
- Plain radiographs, including anteroposterior (AP), lateral, and oblique views, should be obtained to visualize the coalition.
- A calcaneonavicular coalition is best seen on the oblique view (inversion oblique).
- A prominent anterior process of the calcaneus, the “anteater nose” sign, may be seen on the lateral view.4
- Standing AP and lateral views can be included to assess foot alignment (FIG 2).
- A Harris axial view or Salzman hindfoot alignment view can be obtained to assess heel alignment.
- A CT scan should be obtained to rule out a concurrent talocalcaneal coalition or the presence of arthritis in adjacent joints. A CT or MRI may also be useful if the diagnosis is in question.
DIFFERENTIAL DIAGNOSIS

- Flexible flatfoot
- Subtalar arthritis
- Other tarsal coalition (talocalcaneal or other less common ones)
- Tumor or infection involving the subtalar joint
- Idiopathic rigid flatfoot

NONOPERATIVE MANAGEMENT

- Nonoperative management is indicated for all patients with calcaneonavicular coalition at first presentation.
- Painless coalitions need no treatment.
- Initial treatment for painful coalitions consists of activity modification, anti-inflammatory medication, and immobilization in a short-leg walking cast for 4 to 6 weeks.

SURGICAL MANAGEMENT

- The indication for surgical management is persistence of pain despite nonoperative management.
- The main goals of treatment are, primarily, elimination of pain and restoration of function.
- Restoration of subtalar motion is a secondary goal.
- Restoration of arch height is unlikely after resection.

Preoperative Planning

- All imaging studies are reviewed.
- An examination of subtalar motion may be performed under anesthesia to serve as a comparison to the examination immediately after resection.

INCISION AND DISSECTION

- The procedure can be done under tourniquet control if desired.
- An oblique incision is made along the lateral side of the foot between the extensor tendons and the peroneal tendons, directly overlying the anterior process of the calcaneus (TECH FIG 1A).
- The skin and subcutaneous tissue are incised sharply, taking care not to undermine the tissues.
- The extensor digitorum brevis is exposed and followed proximally to its origin at the sinus tarsi (TECH FIG 1B,C).

Positioning

- The patient is positioned supine with a bump under the hip of the operative side to slightly internally rotate the leg.
- If subcutaneous fat autograft is to be used as an interposition material after resection, the limb should be prepared up to the buttocks and a sterile tourniquet should be used (FIG 3).
- Alternatively an eschmarch tourniquet may be used just proximal to the ankle.

Approach

- The approach involves exposure and resection of the entire coalition.
- A graft material is interposed between the ends of the resected bone consisting of local muscle (peroneus brevis) or autologous fat.
The coalition is localized with a needle and confirmed fluoroscopically. The coalition is resected with a small osteotome. When performing the medial cut, care is taken to avoid damaging the adjacent articular surface of the talar head.

- Fibrofatty tissue within the sinus tarsi is exposed.
- This fibrofatty tissue is incised and reflected distally along with the attached origin of the extensor digitorum brevis, exposing the anterior process of the calcaneus and the calcaneonavicular coalition (TECH FIG 1D).

- The ends of these two cuts should not meet, as the goal is to resect a trapezoidal piece and not a triangular piece.
- The coalition is resected with a small osteotome. When performing the medial cut, care is taken to avoid damaging the adjacent articular surface of the talar head.

- Fluoroscopic confirmation of the coalition is obtained by placing a surgical instrument or needle directly over it (TECH FIG 1E).

- Bone wax is placed over the exposed cut bone surfaces.

The extensor digitorum brevis is retracted distally and any remaining fibrofatty tissue from the sinus tarsi is retracted proximally.

- A small osteotome is used to remove a trapezoidal piece of bone (TECH FIG 2A,B).

- The first cut is made in the region of what would be the middle of the anterior process of the calcaneus. This cut should be inclined about 40 to 60 degrees from the vertical relative to the plantar surface of the foot and directed medially toward the lateral aspect of the navicular, deep within the wound.

- The next cut is made at the most lateral aspect of the navicular, directed toward nearly the same point as the first cut.

- The ends of these two cuts should not meet, as the goal is to resect a trapezoidal piece and not a triangular piece.
- When making these cuts, especially the medial one, care must be taken to avoid injuring the articular cartilage of the talar head, which lies directly medial and proximal to the osteotome.
- Attention must also be paid to removing sufficient bone so that there is a visible space between the calcaneus and navicular, which is confirmed fluoroscopically on the inversion view. After resection, the lateral edge of the navicular should line up with the lateral aspect of the talar neck and the medial edge of the anterior process of the calcaneus should line up with the medial edge of the cuboid.
- Remaining bone is removed as necessary with rongeurs (TECH FIG 2C).

- Bone wax is placed over the exposed cut bone surfaces.
INTERPOSITION OF FAT GRAFT

- A piece of subcutaneous fat can be taken from just beneath the buttock crease. Use of this donor site allows for a cosmetic incision with minimal donor site morbidity. There is always abundant fat in this location and there are no neurovascular structures at risk during this dissection.
- A transverse incision is made at the base of the buttocks while an assistant elevates the limb.
- A piece of subcutaneous fat about 2 cm in diameter is removed and placed directly into the gap that has been created (TECH FIG 3).

Interposition of Peroneus Brevis Muscle (Alternative Technique)

- After the coalition has been resected, heavy absorbable sutures are woven through the proximal end of the peroneus brevis that had been detached from its origin.
- The ends of the sutures are passed through Keith needles.
- The Keith needles are passed through the space that has been created in the depth of the wound, to exit the medial side of the foot.
- The needles are passed through a piece of sterile felt and a button and the sutures are sewn over the button, drawing the muscle into the gap where the calcaneonavicular coalition was previously (TECH FIG 4).

WOUND CLOSURE

- The tourniquet is released and hemostasis is obtained.
- If fat was used as graft material, the extensor digitorum brevis is sewn back down anatomically to its origin with absorbable suture.
- Subcutaneous tissue and skin are closed in standard fashion.

PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Approach</th>
<th>The surgeon should avoid undermining the skin to prevent wound complications.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Coalition resection</td>
<td>To prevent bone regrowth, the surgeon should ensure adequate bone is removed so that there is a visible gap between the calcaneus and navicular. The surgeon should be cognizant of the local anatomy, specifically the location of the head of the talus, to avoid damaging the talus when making cuts.</td>
</tr>
<tr>
<td>Graft harvesting and placement</td>
<td>When using fat graft, sufficient fat should be removed to fill the defect created by the resection.</td>
</tr>
</tbody>
</table>

POSTOPERATIVE CARE

- The patient is placed in a cast or splint for 2 to 3 weeks to allow the graft to consolidate and the wound to heal.
- Progressive weight bearing is allowed after cast removal, and range-of-motion exercises are performed to address subtalar motion.

OUTCOMES

- Greater than 90% good or excellent results have been reported in most series.²
- Poor results with persistent pain are attributed to failure to resect adequate bone or the presence of concurrent arthritis in the midfoot or hindfoot.³
COMPLICATIONS

- Failure to resect adequate bone
- Injury to adjacent articular cartilage
- Wound-healing complications
- Recurrence of the coalition

REFERENCES

DEFINITION

- A talocalcaneal coalition is an abnormal connection between the talus and the calcaneus that limits subtalar motion.
- As is the case for calcaneonavicular coalitions, which are described in the prior chapter, talocalcaneal coalitions typically result in a rigid flatfoot that is sometimes painful.

ANATOMY

- Talocalcaneal coalitions occur within the subtalar joint, most commonly involving the middle facet. These connections can be bony, cartilaginous, or fibrous and can involve any amount of the joint.
- The size of the coalition is described with respect to the percentage of the subtalar joint that is coalesced.

PATHOGENESIS

- Like calcaneonavicular coalitions, the cause of talocalcaneal coalitions remains unknown, but they may be the result of failure of segmentation during fetal development.
- Although they are presumed to be congenital in nature, symptoms typically do not appear until early adolescence, ages 12 to 16.
- It is unclear why some coalitions become painful. One theory suggests the possibility of altered talar joint kinematics placing additional stress on adjacent joints. Another is the development of microfractures or stress fractures through the coalition over time, rendering them painful.

NATURAL HISTORY

- Most talocalcaneal coalitions are asymptomatic. They may result in the development of a rigid flatfoot, characterized by valgus alignment of the heel, abduction of the forefoot, loss of the arch, and failure of the arch to reconstitute on toe-rise or when non-weight bearing.
- Pain secondary to talocalcaneal coalitions usually develops between 12 and 16 years of age.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients typically describe pain in the foot that is activity related; it is exacerbated by walking on uneven surfaces and relieved by rest.
- This pain may be generalized to the midfoot or can be specifically localized to the medial aspect of the hindfoot and ankle.
- Patients may also complain of lateral pain at the tip of the fibula.
- There may be a history of progressively worsening out-toeing or loss of the arch.
- The clinician should observe the patient’s gait for an antalgic pattern and torsional alignment, with specific attention to foot position during stance.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs should be obtained in an attempt to identify the coalition. These should include anteroposterior (AP), lateral, oblique, and Harris axial views.
- A talocalcaneal coalition is best seen on the Harris axial view, but it may be difficult to obtain the exact orientation to adequately visualize the middle facet.
- On the lateral view there may be a continuous C-shaped line along the talar dome and into the posterior facet (C-sign).
- On the AP and oblique view one may identify other concurrent coalitions.
- Standing AP and lateral radiographs and a Salzman hindfoot alignment view can be useful for assessing foot alignment, especially hindfoot valgus.
- A CT scan is mandatory to clearly visualize the coalition and determine the percentage of the subtalar joint that is involved.
- An MRI may be useful if the diagnosis is equivocal and a cartilaginous or fibrous coalition is suspected.

DIFFERENTIAL DIAGNOSIS

- Flexible flatfoot
- Subtalar arthritis
- Other tarsal coalition (calcaneonavicular or less common ones)
- Tumor or infection involving the subtalar joint
- Idiopathic rigid flatfoot

NONOPERATIVE MANAGEMENT

- Nonoperative management is indicated for all patients with talocalcaneal coalition at first presentation.
- Painless coalitions need no treatment.
- Painful coalitions may benefit from activity modification, anti-inflammatory medication, and immobilization in a short-leg walking cast.
The indication for surgical management is persistence of pain despite nonoperative management.

The main goals of treatment are, primarily, elimination of pain and restoration of function.

Restoration of subtalar motion is a secondary goal.

Restoration of arch height is unlikely following excision of a talocalcaneal coalition.

Preoperative Planning

- All imaging studies are reviewed.
- An examination of subtalar motion may be performed under anesthesia to compare to the motion obtained after excision of the coalition.

Positioning

- The patient is positioned supine on the operating table.
- Generally the leg assumes an external rotation posture at rest so that the medial ankle and hindfoot are easily accessible. If this is not the case, then a small bump can be placed beneath the opposite hip.
- A tourniquet is placed on the upper thigh or an eschmarch tourniquet may be used just proximal to the ankle.

Approach

- The approach involves identification of the entire coalition with delineation of the normal cartilage on either side.
- The bone representing the coalition is exposed and subcutaneous fat or a portion of the flexor hallucis longus is interposed.

INCISION AND DISSECTION

- The procedure can be done under tourniquet control, if desired.
- A straight horizontal incision is made along the medial aspect of the hindfoot centered over the sustentaculum tali.
- The incision should extend from the anterior margin of the Achilles tendon to the prominence of the navicular tuberosity (TECH FIG 1A).

- If any fibers of the abductor hallucis are encountered, they are retracted plantarly.
- The tibialis posterior tendon is identified dorsally (TECH FIG 1B).
- The flexor digitorum longus tendon is identified and its sheath is opened along the length of the incision (TECH FIG 1C).
EXPOSURE OF THE TALOCALCANEAL COALITION

- The talocalcaneal coalition lies just dorsal to the sustentaculum tali and deep to the sheath of the flexor digitorum longus.
- While retracting the flexor digitorum longus tendon plantarly, palpate the sustentaculum tali.
- The coalition lies deep to the medial portion of the sheath of the flexor digitorum longus and periosteum.
- The medial aspect of the flexor digitorum longus sheath, along with the periosteum just deep to it, should be incised slightly dorsal to the prominence of the sustentaculum tali, taking care to maintain an adequate layer to be used later for closure (TECH FIG 2A,B).
- Because the normal joint in this area is now obscured by the coalition, it is often difficult to determine the appropriate level for bone resection without first identifying some normal joint space.
  - If this is the case, the dissection may be carried posteriorly and anteriorly to identify the posterior and anterior facets of the subtalar joint, respectively, so that the normal articular cartilage in these areas can be identified.
  - The posterior facet can be identified by retracting the neurovascular bundle either posteriorly or anteriorly and dissecting deep to it.
  - The anterior facet is identified just proximal to the talonavicular joint and plantar to the talar neck.
  - Occasionally a stripe of cartilage can be identified traversing through the center of the coalition. In these cases, resection may proceed directly to this level.
- The Achilles tendon is then identified at the most posterior aspect of the wound.
- At this point all of the critical anatomic structures have been identified and the coalition can now be exposed.

- The neurovascular bundle is identified just posterior to the flexor digitorum longus.
- The flexor hallucis longus tendon sheath can be opened if it is to be used as interposition material. If autologous fat graft is to be used, then this step is unnecessary.
- The neurovascular bundle is identified just posterior to the flexor digitorum longus.
- The flexor hallucis longus tendon sheath can be opened if it is to be used as interposition material. If autologous fat graft is to be used, then this step is unnecessary.
- The Achilles tendon is then identified at the most posterior aspect of the wound.
- At this point all of the critical anatomic structures have been identified and the coalition can now be exposed.

TECH FIG 1 • A. Incision marked on the skin. B. The posterior tibial tendon (superior) and flexor digitorum longus tendon (inferior). C. The neurovascular bundle is seen directly posterior to the posterior tibial tendon.

- The neurovascular bundle is identified just posterior to the flexor digitorum longus.
- The Achilles tendon is then identified at the most posterior aspect of the wound.
- At this point all of the critical anatomic structures have been identified and the coalition can now be exposed.

- The neurovascular bundle is identified just posterior to the flexor digitorum longus.
- The Achilles tendon is then identified at the most posterior aspect of the wound.
- At this point all of the critical anatomic structures have been identified and the coalition can now be exposed.

- The neurovascular bundle is identified just posterior to the flexor digitorum longus.
- The Achilles tendon is then identified at the most posterior aspect of the wound.
- At this point all of the critical anatomic structures have been identified and the coalition can now be exposed.
TECH FIG 2 • A,B. The medial aspect of the sheath of the flexor digitorum longus and the periosteum overlying the talus are incised. C. The posterior facet is visualized (just posterior to the curette) and the coalition is entered with a curette. D,E. The coalition has been removed and there is a visible gap between the talus (superior) and calcaneus (inferior). Just beyond the excised bone, normal articular cartilage can be seen.

INTERPOSITION OF FAT GRAFT

- Next, to retrieve fat graft, the neurovascular bundle is retracted anteriorly, exposing the retrocalcaneal fat between the Achilles tendon and the calcaneus (TECH FIG 3A).
- A piece of fat about 1 cm in diameter is excised from the area.
- This fat is interposed into the space from where the coalition was resected (TECH FIG 3B,C).
- The layer of tissue composed of periosteum and flexor digitorum longus sheath is then repaired over this fat with absorbable sutures helping to secure it in place (TECH FIG 3D).

TECH FIG 3 • A. Retrocalcaneal fat is exposed between the Achilles tendon and the neurovascular bundle and harvested for the graft. B–D. The graft is inserted into the area of the resected coalition and the periosteum is closed over the graft.
INTERPOSITION OF A PORTION OF THE FLEXOR HALLUCIS LONGUS TENDON (ALTERNATIVE TECHNIQUE)

- As an alternative to autologous fat graft, half of the flexor hallucis longus tendon may be interposed.\(^2,4\)
- After completely resecting the coalition and confirming adequate motion of the subtalar joint, the flexor hallucis longus tendon is exposed by opening its sheath just inferior to the sustentaculum tali, if this has not been done during the surgical approach.
- The flexor hallucis longus lies in a groove directly inferior to the sustentaculum tali.
- The flexor hallucis is then split longitudinally but left in continuity along its length.
- The superior half of the tendon is then placed in the gap that has been created where the coalition was resected. Care is taken to ensure that the length of tendon that is split is sufficiently long so that the motion of the flexor hallucis longus is not restricted.
- This is accomplished by moving the interphalangeal joint of the great toe through a range of motion and confirming that motion is not restricted.
- The periosteum from the talus is then sutured to the periosteum from the sustentaculum to prevent the tendon from slipping out of place.

WOUND CLOSURE

- The tourniquet is released and hemostasis is obtained.
- The tendon sheath of the flexor digitorum is closed with fine absorbable sutures.
- Subcutaneous tissue and skin are closed in standard fashion.

PEARLS AND PITFALLS

**Indications**

- The preoperative CT scan should be carefully assessed for the extent of the coalition and the presence of subtalar arthritis. Excision of the coalition is contraindicated if greater than 50% of the joint surface is coalesced or in the presence of subtalar arthritis.
- Hindfoot alignment is determined clinically and radiographically to assess for hindfoot valgus. Excessive valgus has been associated with poor outcomes.

**Approach**

- The incision should be long enough to allow adequate identification of normal subtalar joint.
- The periosteum and medial sheath of the flexor digitorum longus are preserved to secure the graft.

**Excision of coalition**

- The surgeon should identify normal articular cartilage posterior and anterior to the coalition so that the level of resection can be identified.
- Bone is resected from the area where the normal joint can be seen toward the center of the coalition.
- It is possible to resect bone into the body of the talus or calcaneus, missing the coalition, if careful attention is not paid to the level of resection.

**Closure**

- The periosteum and medial sheath of the flexor digitorum longus tendon are repaired to prevent extrusion of the graft.

POSTOPERATIVE CARE

- A splint or short-leg cast is applied.
- The foot is immobilized and the patient should remain non-weight bearing for 2 to 3 weeks to allow for wound healing and consolidation of the graft.
- After that, progressive weight bearing and gentle range-of-motion exercises are initiated, focusing on restoring subtalar motion.

OUTCOMES

- Most series report better than 85% good to excellent results.\(^2,4,5,7\)
- Poor results, characterized by persistent pain, have generally been associated with coalitions of more than 50% of the joint surface, subtalar arthritis, or severe valgus alignment of the heel in excess of 21 degrees.\(^3,7\)

COMPLICATIONS

- Failure to adequately resect the coalition
- Recurrence of the coalition
- Residual pain or stiffness due to pre-existing subtalar arthritis

REFERENCES

DEFINITION
- Clubfoot, also known as congenital talipes equinovarus, occurs in approximately 1 in 1000 live births.
- The clubfoot contains four identifiable components that are easily remembered using the acronym CAVE (cavus, adductus, varus, and equinus). Idiopathic clubfoot contains each of the four components to varying degrees.
  - The so-called postural clubfoot is held by the infant in an equinovarus position, but all components are nearly completely correctable with gentle manipulation and resolve over time without intervention.
  - A small proportion of clubfeet are teratologic, occurring as part of other neuromuscular diseases, such as Larsen syndrome, any of the arthrogryposis syndromes, and spina bifida.
  - A severe type of idiopathic clubfoot, the complex clubfoot, has tighter hindfoot and plantar structures.
  - In 1948 Dr. Ignacio Ponseti began manipulating clubfeet through serial casting, completely correcting the clubfoot deformity. The principles of Ponseti casting lay in gradually stretching the soft tissue structures and gently inducing remodeling of the primarily cartilaginous bones of the hindfoot during immobilization.
  - For the definitive publication on clubfoot and the Ponseti technique, the reader is referred to Dr. Ponseti’s book.⁶
  - The success of the treatment protocol that bears his name has been borne out through over 30 years of follow-up, establishing it as the standard for initial treatment of clubfoot.¹
  - Dr. Ponseti has recently published a modification to his original casting technique that addresses the specific deformities characteristic of the complex clubfoot.⁷

ANATOMY
- The Achilles and posterior tibialis tendons, as well as the posterior and medial ligaments between the calcaneus, talus, and navicular, are thickened and fibrotic.⁶
- The clubfoot contains a number of changes in bony alignment and shape (FIG 1).
  - Relative to normal foot anatomy, the first ray is plantarflexed, generating the cavus deformity. By comparison, all rays are plantarflexed in the complex clubfoot, resulting in full-foot cavus.
  - The navicular is medially displaced on the talus, and the cuboid is medially displaced on the calcaneus as part of the adductus deformity. The medial corners of the head of the talus and the anterior calcaneus are flattened.
  - The calcaneus is inverted under the talus, creating the hindfoot varus, while also being in equinus and elevated in the fat-pad of the heel.
  - In children with unilateral clubfoot, the affected foot is smaller, as is the lower leg, relative to the unaffected side.
  - Up to 85% of clubfeet have an insufficient or absent anterior tibial artery.⁵

NATURAL HISTORY
- The exact cause of the fibrotic changes in clubfoot is unknown.
- Left uncorrected, the weight-bearing surface in a clubfoot becomes the dorsolateral surface.
- Thick callosities develop, and the positioning of the foot creates significant functional disability.

PATIENT HISTORY AND PHYSICAL FINDINGS
- Clubfoot may be identified on prenatal ultrasound as early as 12 to 13 weeks (FIG 2).
- Half or more of clubfeet identified on second-trimester ultrasounds have an association with other anomalies or are syndromic.⁸
  - The exact sensitivity and specificity of prenatal ultrasound are unknown, but there does appear to be variation with gestational age: the false-negative rate is thought to approach 0% but the false-positive rate may be as high 40% during the third trimester.⁸ Cases not found on prenatal ultrasound are readily identifiable at birth.
  - All children with clubfeet should be examined for other findings that may suggest a syndromic or neuromuscular association, such as other contractures or joint dislocations (especially hip dislocation), cutaneous lesions, spinal abnormalities, and abnormal facial features.
  - The clubfoot is easily identified by the combined deformities of cavus, adductus, varus, and equinus.
    - Consider complex clubfoot if a deep midfoot crease and cavus extend across the entire plantar aspect of the foot.
    - A deep heel crease, a nonpalpable calcaneus, and tight varus and equinus may suggest complex clubfoot.
  - The ability to abduct or dorsiflex the foot completely suggests etiologies other than idiopathic clubfoot, such as isolated metatarsus adductus, neuromuscular disease, or focal anatomic abnormalities.
    - The fat pad of the heel will feel empty upon palpation due to equinus positioning of the calcaneus. This is especially dramatic in the complex clubfoot.
    - The lateral head of the talus is easily palpable over the dorsolateral surface of the foot. More laterally, the anterior calcaneal tuberosity is also palpable. Care must be taken in differentiating these two structures because Ponseti casting necessitates free motion of the calcaneus under a talus that is stabilized over its lateral head, whereas pressure at the calcaneal tuberosity blocks calcaneal rotation, allowing only forefoot abduction.
    - The complex clubfoot has a crease that extends completely, or nearly so, across the plantar aspect of the foot. Full foot cavus is present, with plantarflexion of all metatarsals. Also, the heel crease is deeper than that of most other clubfeet. The first ray in the complex clubfoot, if not noticeably retracted at presentation, will become retracted during the initial one or
two correctional casts, as the adductus is corrected, and the cavus will persist. All metatarsals remain plantarflexed. It is important to examine the clubfoot before each casting to evaluate for the adjustments that must be made during casting to correct residual deformities or to identify, and modify casting for, a complex clubfoot.

- A number of classification systems have been introduced, the most commonly used being those of DiMeglio and Pirani. Both have utility in evaluating correction and recurrence, but the predictability of recurrence and final function is still unclear.
- The degree of dorsiflexion and abduction, and the distance of the navicular anterior to the medial malleolus, provide other objective measurements.

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Plain radiographs at birth are not helpful in diagnosing clubfoot because the ossific nuclei of the talus and calcaneus are spherical, so orientation and relationship are not discernible, and the other tarsal bones are unossified.
- Clinical examination is sufficient to diagnose the congenital clubfoot.
- Once full abduction is obtained by casting, if dorsiflexion of more than 10 degrees is present, forced-dorsiflexion lateral films are helpful in differentiating midfoot breach, producing apparent dorsiflexion, from true dorsiflexion occurring at the ankle, suggesting the need for a percutaneous Achilles tenotomy (FIG 3).

DIFFERENTIAL DIAGNOSIS

- Metatarsus adductus
- Neurologic equinovarus or cavovarus deformity
  - Both deformities may be differentiated from clubfoot by absence of the other components of clubfoot.
- Teratologic or syndromic clubfeet (including neuromuscular disorders)
  - Clubfoot deformity may be more difficult to correct or may tend to recur.
  - “Postural” clubfoot
  - Complex clubfoot

NONOPERATIVE MANAGEMENT

- Ponseti casting of the idiopathic clubfoot involves a specific sequence of corrective maneuvers that correct the deformities of the clubfoot in combination.
  - Each manipulation is maintained with a plaster cast.
  - Resolution of the deformities occurs simultaneously, but complete resolution sequentially follows the acronym CAVE.
  - Ponseti casting can be performed successfully in children up to 2 years old, although any correction obtained by casting in older children may reduce the amount of surgery required for complete correction.
  - An open tendo-Achilles lengthening may be more appropriate than a percutaneous tenotomy in children over 2 years old.
  - Long-leg casts should always be used.
  - A short-leg cast should be applied first so that attention is made solely to molding around the ankle before extending the cast above the knee.
  - Padding should be minimal, and plaster is preferable for its ability to be molded precisely to the contours of the foot and ankle.
  - Four to six casts should correct the cavus, adductus, and varus deformities. If correction is not achieved in eight casts or the child pulls back in the casts (FIG 4A), the possibility of an
FIG 3 • A. Dorsiflexion of right clubfoot after five corrective casts, before tenotomy. Dorsiflexion of 10 degrees would appear to be sufficient to avoid Achilles tenotomy. B. Forced dorsiflexion lateral radiograph of same foot. Dorsiflexion of the metatarsals relative to the axis of the talus reveals the source of clinical dorsiflexion. The calcaneus is still in equinus (relative to the tibial axis) and a percutaneous Achilles tenotomy is required to complete the correction. C. Forced dorsiflexion lateral radiograph of the left (uninvolved) foot. The calcaneus is dorsiflexed and the axis of the first metatarsal is almost parallel to the axis. D. Forced-dorsiflexion lateral radiograph of the right foot 3 weeks after the percutaneous Achilles tenotomy. Now the calcaneus is dorsiflexed relative to the tibial axis and what was seen on the pretenotomy radiograph (B).

FIG 4 • A. A complex clubfoot that has pulled back in the cast. The cast was originally trimmed dorsally to the web spaces of the toes. The heel is elevated in the cast and the toes are no longer visible. B. Purple discoloration of toes after application of the first cast, as the cast begins to cool. C. One hour later, the cast temperature has stabilized and the toes are pink.
unrecognized complex clubfoot or improper casting technique should be considered.

- Casting is facilitated by the child being relaxed and calm. Feeding the infant during casting, playing music, or allowing the child to play with toys may assist in this.
  - For breast-fed infants, it is helpful if the family introduces, and uses once daily, a bottle so that one can be used during casting. If a bottle is not tolerated, having the child suck on a finger that has been dipped in sugar water may be successful.
  - Before leaving the clinic, the toes should be checked to make sure they are pink and well perfused.
  - Some toes will become reddish-purple as the casts cool (appearing much like the acrocyanosis present at birth) but will become more pink if the child is bundled and monitored over 1 hour or so (FIG 4B,C).
  - Toes that become more purple and dusky indicate that the cast is too tight and should be reapplied.
  - Casts are changed every 5 to 7 days. The final cast, following percutaneous Achilles tenotomy, is left in place for 3 weeks.
  - Approximately 95% of clubfeet will require a percutaneous Achilles tenotomy to correct the residual equinus once the other components are corrected.
  - Once complete correction is obtained, correction must be maintained by placing the feet in a foot-abduction orthosis (FIG 5A).
  - Some straight-last shoes will need modifications to keep the feet secured (FIG 5B,C), while others require a custom orthosis (FIG 5D) (see “Postoperative Management”).

**SURGICAL MANAGEMENT**

- Percutaneous Achilles tenotomy is required in 95% of idiopathic clubfeet to correct the residual equinus.
- About 20% of patients require anterior tibialis tendon transfer to correct recurrent or persistent dynamic varus deformity.

**Preoperative Planning**

- Degree of dorsiflexion
  - If dorsiflexion is less than 10 degrees, a percutaneous Achilles tenotomy is required to correct the residual equinus.
  - If dorsiflexion is more than 10 degrees, forced-dorsiflexion lateral foot radiographs help to differentiate midfoot dorsiflexion, with residual calcaneal equinus, from true dorsiflexion occurring at the hindfoot (see Fig 3).
- Location
  - The risk of anesthesia must be balanced against the perceived pain and duration of the procedure, as well as the degree of sedation necessary for safe performance of the procedure and optimizing posttenotomy casting.
  - Many institutions prefer local anesthesia with 1% lidocaine, with the procedure performed in the clinic, for infants owing to the high risk of general anesthesia. Others use a eutectic mixture of lidocaine anesthetic cream left in place over the heel. Some institutions require general anesthesia in the operating room, and some providers prefer the guaranteed sedation and pain control afforded in this setting, especially for children over 6 months old.
  - Sedation in a pediatric sedation clinic may be another alternative.

**Positioning**

- The child should be supine on the table with the contralateral leg held out of the way by the parent or an assistant during casting and tenotomy.

**Approach**

- A medial approach is used to avoid the medial neurovascular bundle.
CASTING

Stretching
- Before casting, the foot should be stretched in the same manner as used for immobilization during casting (TECH FIG 1A,B).
  - The thumb of the examiner’s contralateral hand (e.g., the left hand when manipulating the right foot) should be placed over the head of the talus, and the index finger of the other hand should lie along the medial aspect of the first ray with the second through fourth fingers under the plantar aspects of the forefoot.
  - The calcaneocuboid joint should be avoided, so as not to block subtalar motion.
  - The first cast should focus on elevation of the first ray to correct the cavus deformity (TECH FIG 1C).
  - This places the forefoot in supination, locking the midfoot and aligning the forefoot with the hindfoot, providing a lever arm for correction of the hindfoot deformities during later abduction maneuvers.
  - Some of the adductus may also be corrected during the first casting.

Lower-Leg Cast Application
- A thin layer of cotton padding should be applied.
  - The padding is wrapped three times around the toes distally, then extended proximally over the foot and lower leg to pad with no more than two layers of padding.
  - The foot should be held in the position to be casted throughout (TECH FIG 2A). The popliteal fossa should be avoided proximally.
  - A thin layer of plaster is applied over the foot and lower leg.
  - The plaster may be applied more loosely over the toes but should be snug over the hindfoot and ankle to immobilize the foot properly and allow for precise molding (TECH FIG 2B).

- Avoid making the cast too snug so as to impair venous return or apply pressure on the fat pad of the heel.
- The lower-leg cast should be precisely molded around the malleoli and above the calcaneus posteriorly using the index and middle finger of the same hand as the thumb that is immobilizing the talus.
- Do not apply pressure over the fat pad of the heel.
- Throughout, the foot should be held in the position of correction, but the fingers should be in fairly constant motion to prevent pressure spots within the minimally padded cast.
Completing the Cast

- Once the lower-leg cast has set, padding should be applied over the rest of the leg up to the groin, again in no more than two or three layers.
- The knee should be held at 90 degrees, and the lower leg should be in slight external rotation.
- Padding should be minimized in the popliteal fossa to prevent impingement of the neurovascular structures. The padding should be wrapped three to five times over the proximal thigh to pad adequately.
- Plaster should then be wrapped over the short-leg cast above the ankle and extended proximally over the padded knee and thigh to the groin. A plaster splint of three or four layers of plaster roll should be placed over the knee from the middle of the thigh to the middle of the shin to strengthen the cast against knee extension while minimizing bulk in the popliteal fossa. The plaster is then wrapped distally to incorporate the splint, ending once the lower leg has been completely incorporated.
- The knee should be molded while held at 90 degrees with the lower leg in slight external rotation until set (TECH FIG 3A). Rolling the plaster at the proximal edge of the cast before the plaster sets up completely helps minimize chafing of the thigh.
- The cast should be trimmed distally to expose the toes. The surgeon should confirm that they are pink and well perfused (TECH FIG 3B) before the child is sent home.

A

B

TECH FIG 3 • A. Padding and plaster are applied up to the proximal thigh, incorporating the short-leg cast into a long-leg cast. The knee is flexed to 90 degrees. The proximal margin of the cast is rolled to decrease skin irritation. B. The distal end of the cast is trimmed to the web space of the toes dorsally, revealing pink, well-perfused digits. A plantar toe plate remains.

- Trimming the plaster over the dorsal aspect too far proximally, beyond the web space, may create a tourniquet effect over the forefoot.
- A plantar toe plate should be left to prevent toe flexion and curling, which may facilitate pulling out of the cast.
- Parents should be instructed on signs and symptoms of cast problems before discharge.

Cast Changes and Follow-Up

- Casts are ideally changed every 7 days, although they may be changed as frequently as every 5 days; up to 2 weeks may be tolerated if necessary to accommodate conflicts preventing weekly cast changes.
- Casts should not be removed until just before recasting.
- They can be soaked by the family before coming to the office, then removed with a plaster knife in the clinic.
- Alternatively, dry casts may be removed with a cast saw, using extreme caution.
- Having the parents remove the casts the night before results in varied degrees of recurrence overnight and prolongs casting.
- After the first casting, the cavus deformity should be nearly, or completely, corrected.
- Abduction may be increased.
- Stretching is performed with the forefoot in supination, maintaining alignment of all rays, abducting the foot under the talus.
- The foot is then casted in the newly maintained position, just to where the foot may be comfortably corrected without significant resistance.
- Trying to overabduct the foot during a single casting results in intolerance as the foot tries to return to its position of comfort, and in the worst cases results in pressure sores or vascular compromise of the soft tissues along the medial foot. A keen sense of touch and patience are essential.
- Each subsequent manipulation results in increased abduction of the forefoot and correction of the hindfoot varus (TECH FIG 4A–D).
- Throughout, the forefoot should remain in neutral (appearing supinated due to the hindfoot varus) and the hindfoot in equinus (TECH FIG 4E).
- Dorsiflexion of the calcaneus remains blocked under the neck of the talus until approximately 25 degrees of abduction has been obtained. Dorsiflexion before that point results in midfoot, and not subtalar, dorsiflexion (see Fig 3).
- Subsequent eversion of the calcaneus will bring the forefoot and hindfoot into more neutral positions and dorsiflexion may be obtained by percutaneous Achilles tenotomy.
- Once abduction of 70 degrees is obtained (TECH FIG 4F), correction of the remaining equinus deformity may occur.
- Overabduction to 70 degrees is necessary to accommodate some of the inevitable recurrence, without allowing progression beyond a normal position that would require recorrection.
TECH FIG 4 • A. Adduction is decreased in the second cast. B. By the third cast, the foot is in line with the leg. C. By the fourth casting, the foot is abducted 20 degrees and held in this position with the cast. D. With the fifth cast, the foot is now held at 45 degrees of abduction. E. Before the tenotomy, the foot remains in plantarflexion throughout abduction. F. After removal of the fifth cast, the foot can be abducted 70 degrees and is ready for percutaneous Achilles tenotomy. The amount of dorsiflexion in this foot is seen in Figure 3.

COMPLEX CLUBFOOT
- The complex clubfoot may not be immediately recognizable at presentation.
- Correction usually begins using the standard maneuvers, elevating the first ray with the first cast and continuing abduction with the second cast.
  - Within one or two casts, the foot begins to clearly demonstrate a demarcation from the expected correction as the cavus persists and evolves, involving plantarflexion of all metatarsals, and the first ray becomes retracted.
  - At this point, the technique must be modified.
- In the complex clubfoot, the tight plantar intrinsics and toe flexors induce full-foot cavus. This is exacerbated by the tight hindfoot structures, which also limit correction of the varus to just beyond neutral.
- As a result, the casting technique must be modified not only to correct these features, but also to decrease the propensity for pulling out of even long-leg casts.
- Lateral counterpressure still occurs at the lateral head and neck of the talus, but stabilization of the fibula should also occur.
- The index finger of the contralateral hand (eg, the examiner’s left hand when manipulating a patient’s right clubfoot) should be flexed at 90 degrees at the proximal interphalangeal joint and placed posterior to the distal fibula.
- The thumb of the same hand is placed just anterior to the lateral malleolus along the neck of the talus.
- As the foot begins to approach neutral, the full-foot cavus, along with the dramatic equinus, can pose significant casting difficulties.
- The foot becomes contiguous with the lower leg, absent any ankle dorsiflexion, and the cavus short-
ens the foot, making it even more difficult to immobilize.

- A posterior splint of three or four layers of plaster should be applied under the plantar surface of the foot, extending from beyond the tips of the toes proximally over the posterior lower leg.
- As in the upper-leg portion of the traditional cast, the posterior splint about the foot strengthens the plantar portion of the cast against the forceful plantarflexion of the complex clubfoot without increasing bulk over the anterior ankle, which may impede molding and immobilization.
- Then, a thin layer of plaster may be wrapped in the usual manner to encompass the foot and lower leg. A minimal amount of plaster should be used because precise molding is even more important for the complex clubfoot.
- The pads of the thumbs of both hands may be placed under the forefoot, with the pads of the index fingers placed over the dorsal surface of the talar neck, anterior to the medial and lateral malleoli, with the pads of the middle fingers posterior to the malleoli. The forefoot is then forcefully dorsiflexed against the counterpressure over the dorsal talar neck, enough to produce blanching of the digits (presumably due to tension constriction of the posterior tibial and peroneal arteries) (TECH FIG 5A).
- Further counterpressure to dorsiflexion is applied over the anterior thigh above the flexed knee.
- Upon release of dorsiflexion pressure after setting of the cast, the slight relaxation of the cast will result in revascularization of the digits (TECH FIG 5B).
- Care should be taken not to abduct the foot beyond 45 degrees because the tight hindfoot prevents further progression of the hindfoot into valgus, and abduction of the forefoot only occurs.
- On extending the cast up over the lower leg, the knee should be flexed to 110 degrees to minimize the ability to pull out of the cast. An anterior plaster splint over the thigh and knee should be used just as in the traditional technique.
- Tenotomy occurs once the cavus and adductus deformities are corrected, and about 40 degrees of abduction is obtained.
- Attempting to abduct the complex clubfoot beyond 40 degrees results in no further hindfoot correction and only overabducts the forefoot, making immobilization of the foot in the cast more difficult.

TECH FIG 5 • A. When casting the complex clubfoot, to correct the full-foot cavus, a dorsiflexion force is applied to dorsiflex at the midfoot. The fat pads of both thumbs are placed under the heads of the metatarsals, with the index fingers over the dorsal aspect of the talar neck, anterior to the medial and lateral malleoli, with the pads of the middle fingers posterior to the malleoli. The forefoot is then forcefully dorsiflexed against the counterpressure over the dorsal talar neck, enough to produce blanching of the digits (presumably due to tension constriction of the posterior tibial and peroneal arteries) (TECH FIG 5A).

PERCUTANEOUS ACHILLES TENOTOMY

- The tenotomy should occur 1 to 1.5 cm above the insertion of the Achilles on the posterior tuberosity of the calcaneus.
- In many feet, this is 1 to 1.5 cm above the posterior heel crease.
- Performing the tenotomy too low results in damage to the posterior calcaneal tuberosity.
- For procedures in the clinic, local anesthesia must be used.
- A small amount of 1% lidocaine may be injected locally over the tendon at the site of blade insertion before the procedure, taking care not to inject so much as to obscure the ability to discern the Achilles tendon for the procedure (TECH FIG 6A). Usually less than 0.05 mL is sufficient.
- Alternatively, a eutectic mixture of lidocaine anesthetic cream may be used topically. It should be left in place for at least 45 minutes for maximal effect. Blanching of the skin correlates with the anesthetic effect.
- An assistant should hold the foot in maximal dorsiflexion to increase tension on the Achilles tendon, making it
more easily palpable and able to be transected (TECH FIG 6B).

- A second assistant should hold the contralateral leg and foot out of the field.

- A thin, sharp scalpel should be used to perform the tenotomy. Cataract surgical blades (5100 or 5400 Beaver blades) are well suited for this procedure, although an 11 blade is also acceptable. One of two techniques may be used to insert the blade:
  - The blade of the scalpel may be inserted perpendicular to the skin, anterior to the Achilles tendon, from the medial side, with the blade itself oriented parallel to the longitudinal axis of the tendon. The blade must be advanced far enough to pass beyond the lateral side of the tendon so that complete transection occurs. Once advanced far enough, the blade may be rotated in place, orienting the blade perpendicular to the tendon (TECH FIG 6C).
  - Alternatively, the blade may be advanced anterior to the tendon at a 45-degree angle to the skin, again advancing the tip of the blade deep enough to pass the lateral side of the tendon, but with the blade oriented perpendicular to the tendon from the outset. The handle of the scalpel may then be lifted ventrally, bringing the blade perpendicular to the skin, resting against the tendon (TECH FIG 6D).
E. Transection of the Achilles tendon of the left foot. Pressure is applied with the contralateral thumb, pressing the tendon onto the blade, resulting in tendon transection. The level of the tenotomy is 1 cm above the posterior heel crease. F. The foot is in plantarflexion before the tenotomy. G. After the tenotomy, 30 degrees of dorsiflexion is obtained. In extreme dorsiflexion the digits blanch, presumably due to impingement of the posterior tibial artery. Decreasing dorsiflexion just a few degrees resulted in reperfusion. H. During application and molding of the short-leg cast, the foot should be held in maximum dorsiflexion and abduction. An assistant provides counterpressure above the knee. Dorsiflexion pressure is applied only over the plantar aspect of the midfoot and forefoot and the heel remains untouched, while the cast is molded around the ankle with the fingers of the other hand.

- Once the blade is oriented perpendicular to the fibers of the Achilles tendon, the safest maneuver involves pressing the tendon onto the blade using the contralateral thumb (TECH FIG 6E).
- Complete transection often results in a palpable “pop,” release of the Achilles tendon, and an immediate increase of 15 to 20 degrees of dorsiflexion (TECH FIG 6F). A palpable defect in the tendon confirms complete transection.
- If incomplete transection occurs, the tendon should be revisited, adjusting blade position as necessary, to complete the release.
- Care should be taken not to pull the blade through the tendon lest laceration of the overlying skin occur once the resistance of the tendon disappears following transection.
- The Betadine should be cleansed from the skin to prevent Betadine burns to the neonatal skin, and pressure should be applied to the incision site to stop all bleeding before cast application.
- The foot should now be held in the new position of maximum dorsiflexion and abduction.
- In some cases, the increased dorsiflexion will increase traction on the solitary posterior tibial artery as it passes under the medial malleolus, constricting it and resulting in blanching of the digits (TECH FIG 6G).
- The lower leg is wrapped with sterile cotton in the usual manner, accommodating the increased dorsiflexion.
- The plaster is applied in the usual manner, and the cast must be molded well at the anterior ankle to accommodate the increased dorsiflexion and prevent pulling back in the cast (TECH FIG 6H).
- For the complex clubfoot, the posterior plaster splint should be used in the short-leg cast.
- On release of dorsiflexion pressure after setting of the cast, the slight relaxation of the cast will result in revascularization.
- If revascularization does not occur, the cast may need to be removed and reapplied. Although maximum dorsiflexion is prevented because of vascular compromise, what is gained is usually sufficient for adequate correction without the need for a second tenotomy or later recorrection.

Casting

- Extension of the cast above the thigh as a long-leg cast should occur with the knee in the usual 90 degrees of flexion, first with padding (TECH FIG 7A) and then with plaster, holding the lower leg in slight external rotation (TECH FIG 7B).
- The complex clubfoot should have the knee flexed at 110 degrees.
- An anterior knee splint should be used in both cases.
- The posttenotomy cast should be left on for 3 weeks before removal to allow tendon healing.
- Frequently, blood seeps through the cast and becomes visible, and parents should be alerted to this.
- Persistent bleeding, resulting in a spot above the heel larger than a quarter in size, may signify injury to vascular structures on the lateral aspect of the foot, rarely requiring any intervention other than further assessment.²
- When the cast is removed, complete correction should have been obtained (TECH FIG 7C,D).
A. Cotton padding is applied from the proximal edge of the short-leg cast up to the groin. B. With extension to the long-leg cast, the lower leg is held in slight external rotation, and the knee is held at 90 degrees of flexion. The foot is now in maximum dorsiflexion and abduction. C, D. Three weeks after tenotomy, after the final cast is removed, complete correction is obtained. C. The foot abducts 70 degrees. D. The foot actively dorsiflexes 20 degrees.

**PEARLS AND PITFALLS**

Failure to correct the cavus deformity with initial casting

- Failure to elevate the first ray will result in worsening cavus during abduction, and only the forefoot will abduct. The hindfoot varus will fail to correct. The foot will then pull back in the cast. The same deformities will occur in the complex clubfoot if the full-foot cavus is not corrected before or during early abduction.

Toes turn purple after cast application (see Fig 4)

- Some neonatal feet have poor vascular control and will turn purple as the cast cools. Don’t be too hasty to remove the cast. Bundle the child, elevate the feet, and recheck every 15 minutes ×4. As the cast dries, the toes should become pink (see Fig 4). Increasing purplish discoloration indicates a cast that is too tight and should be reapplied.

An older child who resists casting

- A child who fights casting prevents good molding and too much motion may prevent the cast from setting up in the desired position. A quiet room with music may relax the child. Likewise, entertaining the child with a toy may distract him or her. Feeding may also be helpful. Older children often do better if sitting slightly upright, propped against a pillow, or even in a parent’s lap.

Child pulling out of foot-abduction orthosis

- Add padding in the heel, above the posterior calcaneal tuberosity, use a shoe with a heel cutout, or both (see Fig 5C). If the child has a strong propensity for toe curling, try a Plastizote plate under the toes to keep them extended. For persistent intolerance, try using only the strap without the tongue. Maintenance of complex clubfoot is extremely difficult and may require a custom brace (see Fig 5D).

Child cries while in casts or in bar and shoes

- Make sure the toes are well perfused. Discomfort for 24 hours after the first casting or tenotomy is common and easily relieved with acetaminophen. The child should be seen and the cast might need to be removed if discomfort persists for >48 hours.
- If the child is in an orthosis, examine the feet for sores. If the orthosis is removed whenever crying occurs, the child may associate crying with subsequent bar removal. Feet may be hyperesthetic after casting: massage during diaper changes and other times out of the orthosis accelerates desensitization.

Recurrence

- Monitor for decreases in abduction and dorsiflexion.
- Treating an early identified, minimal recurrence with stretching by the parents with every diaper change may prevent progression. Later or more marked recurrence should be treated with recasting and possibly a second percutaneous tenotomy. For recurrence in older children, an open Achilles tendon lengthening may be more appropriate for feet with minimal dorsiflexion. For residual dynamic varus, a transfer of the anterior tibialis tendon may be necessary (see Chap. PE-92).
POSTOPERATIVE CARE

- After removal of the posttenotomy cast, the child should immediately be placed in a foot-abduction orthosis. Most fully corrected idiopathic clubfeet will tolerate standard orthoses consisting of open-toed, straight-last shoes connected by a bar.
- In the case of bilateral corrected clubfeet, both shoes should be placed in abduction and external rotation on the bar to the degree of comfortable correction, typically 55 to 60 degrees (see Fig 5D).
- For unilateral clubfoot, only the shoe of the affected foot is placed near the extreme of abduction. The shoe of the uninvolved, normal foot is placed at 35 degrees of abduction and external rotation. The shoes should be placed at shoulder width on the bar.
- Mounting the shoes on the bar such that the buckle of the anterior ankle strap is on the medial aspect of the foot cases application of the orthosis (see Fig 5D).
- In cases of unilateral clubfoot, application of the orthosis is easier if the affected foot is placed into its shoe first, followed by the normal foot. In bilateral cases, one foot is usually “tighter” (more resistant to correction or had less correction from the tenotomy), and this is the one that should be placed in the orthosis first.
- The anterior ankle strap secures the foot in the shoe and should be tightened sufficiently to prevent pulling the foot out of the shoe. The laces should be pulled only tight enough to conform the shoe to the foot. Tightening further may cause venous congestion and extreme discomfort.
- If the foot is not secured in the shoe, Plastizote pads should be used. Usually a pad placed in the heel of the shoe, positioned so that the inferior edge rests just above the posterior tuberosity of the calcaneus, is sufficient.
- If necessary, pads on the tongue and/or under the toes may provide further limitations to pulling the foot out of the shoe.
- In some cases, the tongue provides an obstruction to securing the foot, and removing the tongue may actually improve the ability of the strap to secure the foot.
- Other modifications that may help prevent pulling out include lacing the shoes from the ankle down to the toe, slightly decreasing the degree of external rotation of the shoes (no less than 45 degrees), or widening the bar slightly beyond shoulder width.
- Only a single, thin pair of socks should be worn with the shoes. For the first 1 or 2 days, two socks may be used to prevent blisters (much like the double-sock method used by runners), but thereafter only one pair should be used.
- Thick, well-padded socks prevent adequate securing of the foot and make it easier to pull the foot out of the shoe.
- For the first week, the orthosis and socks should be removed with every diaper change to inspect the feet for evidence of developing pressure sores.
- Red spots that do not disappear within 5 minutes signal a potential problem spot and require refitting of the shoes with Plastizote or repositioning on the bar.
- Care should be taken to remove the orthosis when the child is calm to prevent the child from associating crying with subsequent removal, resulting in persistent resistance to orthosis wear with unrelenting crying.
- After casting, the leg and foot are hyperesthetic.
- Massaging the leg, initially deeply and progressing to light touch, with each diaper change during the first week helps with desensitization.
- The lower leg may also develop intermittent purple discoloration when dependent to gravity after casting. This usually resolves over the first month out of casts.
- After the first week, the orthosis should be worn full time, but it may be removed once daily for bathing and a short period of play (1 to 2 hours).
- Full-time wear continues for 3 to 4 months to maintain correction.
- Tighter feet, or those more difficult to correct, may benefit from periodic stretching in dorsiflexion and abduction whenever the orthosis is removed.
- Children should be re-examined in and out of the orthosis after 1 month, then 2 months later.
- After 3 months of full-time wear and maintenance of full correction, children wear the orthosis only during periods of sleep, at nighttime, and during naps.
- Children should be examined every 3 to 6 months, depending on the level of concern regarding recurrence, until bar and shoe wear is complete.
- Any episodes of recurrence warrant recasting as soon as identified.
- Casting is performed in the usual manner to obtain complete correction again.
- Casting is usually sufficient to correct the recurrence. Rarely, a repeat percutaneous tenotomy is necessary for more severe recurrence. Once complete correction is again obtained, orthosis wear occurs for 3 months full time before resuming part-time wear.
- Straight-last shoes may be worn until the child’s toes curl over the edge of the shoe. Then the next appropriate size should be fitted and attached to the bar.
- Part-time wear continues until the child is 4 years old, when orthosis wear may be discontinued. Children should be monitored for recurrence, which occurs rarely after 4 years old.
- Complex clubfeet almost always pull out of standard straight-last shoes. A variety of newer bar-and-shoe constructs have been developed to address the limitations of current standard orthoses, including one developed by Dr. Ponseti (see Fig 5D).

OUTCOMES

- A corrected clubfoot tends to recur to its original position, requiring maintenance of correction in the orthosis. Noncompliance with bar-and-shoe wear increases the likelihood of recurrence to more than 80%. Compliance is increased with close follow-up and explicit discussions with the family and all caregivers.3
- Twenty percent to 50% of corrected clubfeet will require anterior tibialis tendon transfer to correct dynamic varus present during ambulation (see Chap. PE-92).

COMPLICATIONS

- Cast sores, cast saw burns
- Prolonged casting or pulling back in the cast due to improper technique, unrecognized clubfoot, or failure to modify casting for complex clubfoot
- Overabduction from unrecognized complex clubfoot or overabduction in foot abduction orthosis (beyond degree of correction)
- Posterior tibial artery impingement
- Peroneal artery or lesser saphenous vein laceration during tenotomy
- Pulling back in cast from poor cast molding, unrecognized complex clubfoot, or not enough knee flexion in long-leg cast if complex clubfoot
- Recurrence due to incomplete correction or lack of orthosis wear

REFERENCES

Clubfoot, or talipes equinovarus, is a congenital or acquired deformity in which the foot is stiffly positioned in hindfoot equinus and varus, and forefoot varus, supination, and plantarflexion. When the deformity is not corrected, the patient limps, bearing weight on the lateral forefoot. This can limit ambulation and lead to foot and ankle pain, abnormal calluses, and ulcers and infections. The deformity may present as an isolated or syndromic birth defect. Clubfoot has been documented in conjunction with diagnoses of polio, spina bifida, cerebral palsy, as well as other disorders.

The exact cause of clubfoot remains unknown. Many theories and their detractors can be found in the literature. The displacement of these bones differs, producing varying amounts of four different positional deformities: cavus, adductus, varus, and equinus. Eventually, the abnormal forces and positions lead to plantarflexion and medialization of the talar neck. Weakness and underdevelopment of the foot and calf to varying degrees results. While radiographic measurements are hard to reproduce, the anteroposterior (AP) and lateral talocalcaneal angles are reduced from about 28 degrees to about 5 degrees in children with clubfoot.

The deformity of clubfoot is identified at birth as unilateral or bilateral hindfoot equinus and varus and midfoot supination, varus, and equinus. To perform the examination, the leg is extended at the knee and the foot is then dorsiflexed. The foot-to-tibia angle is measured to assess the amount of equinus in the frontal plane and the amount of heel varus in the sagittal plane. The dorsolateral aspect of the midfoot is palpated to locate the talar head. The forefoot is then manipulated to determine if the forefoot can be reduced onto the talar head. The lateral rotation of the foot–thigh angle can be assessed by flexing the knee and ankle to 90 degrees and gently laterally rotating the foot. The angle is measured.

The lateral rotation of the foot–thigh angle can be assessed by flexing the knee and ankle to 90 degrees and gently laterally rotating the foot. The angle is measured.
These examinations do not determine a classification but rather the stiffness of the foot and the amount of improvement attained with serial casting and surgical intervention.

The clinician should investigate associated anomalies, such as spina bifida, spasticity, muscular dystrophy, arthrogryposis, and so forth. By understanding the cause, the likelihood of treatment success can be predicted.

The clinician should observe the shape and size of the foot. The clubfoot is generally shorter and wider than a normal foot.

Examination reveals equinus and varus of the ankle and midfoot. Calf atrophy is expected, particularly in the older child (FIG 1A–C).

Treatment may be altered depending on the presentation of the clubfoot.

Range of motion: equinus

Ankle motion (dorsiflexion and plantarflexion) is assessed in both knee extension and flexion. The os calcis may remain in equinus (palpation) even though the heel pad appears (observation) to come out of equinus (FIG 1D,E).

The foot may “look” as if the equinus is corrected, but the physician must palpate it to know for sure.

Range of motion: subtalar joint

Range of motion is difficult to measure. The resting alignment of the heel to the talus is usually varus in the untreated clubfoot and 5 to 10 degrees of valgus in the corrected foot. The clinician looks at the sole of the foot to observe midfoot varus. The sole is manipulated to see how flexible it is (FIG 1F,G).

Failure to correct the heel into slight varus indicates incomplete correction of the clubfoot. Overcorrection of the heel into valgus can lead to painful pronation. Residual varus

of the lateral border of the foot may be due to subtalar rotation, varus of the calcaneus, medialization of the cuboid on the calcaneus, or varus deformity of the metatarsals. Correction may be required at the site of deformity.

- Range of motion: forehead on the talar head
  - The foot is palpated dorsolaterally at the lateral midfoot. It usually is lined up with the patella, although plantarflexed. Manipulation is used to reduce the forehead (FIG 1H).
  - The more difficult it is to reduce the forehead onto the talar head, the stiffer the deformity.
- Forefoot supination
  - The clinician observes that the forefoot of the clubfoot appears supinated with respect to the tibia. However, supination relates to the position of the forehead to the hindfoot (FIG 1J).
  - If the forefoot appears 30 degrees to the tibia and there is 30 degrees to the hindfoot varus, then the deformity is hindfoot varus and not supination!
  - It is important to know where this deformity is. Errors in this assessment may lead the surgeon to overcorrect the midfoot or surgically create a pronation deformity.
- Forefoot plantarflexion
  - The physician begins with palpation of the medial column from the first metatarsal to the talar head. Plantarflexion of the forefoot on the hindfoot is measured.
  - In the operated foot, the physician checks for dorsolateral subluxation or dislocation of the navicular on the talar head (FIG 1K).
  - Deformity must be corrected where it is. This assessment, in conjunction with radiographs, will help to assess its location in the soft tissues, the ankle, the bone, or the joints (such as subluxation of the talonavicular joint).

IMAGING AND OTHER DIAGNOSTIC STUDIES

- Sonograms may be used to diagnose clubfoot prenatally. While no prenatal treatment is available, many parents want to know the diagnosis of clubfoot so they can learn about the natural history and treatment options available to them.
- The prenatal ultrasonographic diagnosis of clubfoot may be made if the bones of the lower leg are in the same plane as the plantar surface of the fetal foot. To ensure a correct diagnosis, images in which the leg is extended away from the wall of the uterus should be obtained.
  - This deformity may be seen as early as 12 or 13 weeks.
- Plain radiographic images in the newborn period add little to the physical examination. Films are not reproducible and contribute little to the management.
  - With older children, radiographs may be necessary to treat the deformity effectively, as they can identify fixed individual bone deformities such as flat-top talus, varus deformity of the calcaneus, or dorsolateral subluxation of a triangular navicular on the talar head.
  - The most common images used are those of the talocalcaneal angle in both the AP and lateral planes. Both must be obtained while bearing weight or simulated weight bearing on the affected foot.

DIFFERENTIAL DIAGNOSIS

- Identifying the underlying cause is often helpful. Examination should be complete to identify spinal dysraphisms, syndromes, cerebral palsy, spina bifida, and so forth.

NONOPERATIVE MANAGEMENT

- Most would claim that extensive surgical techniques are necessary in less than 5% of cases.
- Two of the major techniques preferred for nonoperative treatment:
  - Optimal for very young patients, the Ponseti method uses weekly manipulations and cast applications to treat the deformity. About 90% of the patients treated with the Ponseti method will need posterior releases, and about 30% will require additional surgical management after age 2, including repeat posterior release, posteromedial release, and complete subtalar release.
  - Also used predominantly in newborns, the French method incorporates daily manipulation and stimulation of the foot muscles with nonelastic adhesive strapping to correct clubfoot.
  - There will always be the recalcitrant clubfoot that resists methods such as the Ponseti technique. These cases usually fall into the “arthrogrypotic” or “teratologic” category and should be treated with the releases described below.

SURGICAL MANAGEMENT

- All authors agree that the goal of surgical treatment is first to release enough of the tight structures to bring the foot into an anatomically correct position without tension.
- Many will add that muscles should be balanced to help maintain the anatomic position.

Preoperative Planning

- The age of the child will play an important role in what must be done to restore anatomic alignment. Generally, soft tissue releases are adequate from age 2 months to 4 years and in some cases to age 6 years. By the age of 4 years, many of the chieffeet are beginning to show bone deformity, which will block correction after soft tissue releases alone.
- The choice of operative procedure depends on not only the age of the patient, but also the degree of rigidity, the deformities present, and the extent of correction by previous treatment.

Positioning

- The child is placed on the operating table in the prone position.
- The patient is supported using bolsters underneath the shoulders and waist.
- The legs are kept free and the knee is fully extended.

Approach

- Surgical release should begin posteriorly and then continue medially. These areas should reveal the tightest structures in an equinovarus foot.
- As recommended by Henri Bensahel, often the “à la carte” approach is used, in which intraoperative evaluation leads the surgeon to release any and all tight structures. The surgeon must be prepared to do as little or as much as needed to accomplish anatomic realignment.
- For each of the soft tissue releases described in Techniques, it is important to evaluate each foot after each step of the surgical release to determine if the anatomy is corrected or if additional release is necessary.
  - The goal is to do as little or as much of a release as will place the foot in a corrected position without force.
  - Lengthening tendons and then capsules and ligaments at each location will minimize scarring and stiffness.
INCISION

Turco Posteromedial Incision
- The Turco incision allows for access to the medial and posterior portions of the foot (TECH FIG 1).
- The technique begins with a medial incision at the first metatarso-medial cuneiform joint.
- The cut is extended proximally until it is just distal to the tip of the medial malleolus.
- Care is taken to curve the incision in a vertical direction, up the calf to expose the Achilles tendon.
- To reach the lateral side, the subtalar joint must be opened like a book, or a separate lateral incision must be made.

Carroll Medial and Posterolateral Incisions
- The Carroll types of incisions allow medial or more posterolateral access (TECH FIG 2).
- For the medial incision, a triangle is cut that is demarcated by the center of the os calcis, the front of the medial malleolus, and the base of the first metatarsal.
- The incision is made parallel with the base of the triangle, then curved proximal-plantar, and then curved distally over the dorsum of the foot.
- For the posterolateral incision, an oblique incision is created that runs from the midline of the distal, posterior calf to a point between the tendo Achilles and the lateral malleolus.
- A lateral incision may be required to reach the lateral talonavicular joint.

Cincinnati Incision (Author’s Preferred Incision)
- The Cincinnati incision provides the most extensive access to the foot, including medial, posterior, and lateral access (TECH FIG 3).
- The incision begins medially over the talonavicular joint, extending posteriorly at the level of the subtalar joint. It is continued distally to the talonavicular joint laterally and may be extended distally on both the medial and lateral sides.
- The Cincinnati incision is most easily performed with the patient prone. Flexing the knee provides excellent access to the Achilles tendon for Z-lengthening.
- For severely deformed feet (equinus), closure may be difficult.
POSTERIOR SOFT TISSUE RELEASE

- In the exsanguinated prone foot, the posterior portion of the Cincinnati incision is made from the distal tip of the medial malleolus around the posterior ankle to the distal tip of the lateral malleolus.
- The Achilles tendon sheath is incised to expose the Achilles tendon. In a child under 18 months, the tendon can be lengthened by tenotomy, but in the older child it should be lengthened by Z-lengthening.
- To facilitate visualization for a Z-lengthening of the Achilles through the Cincinnati incision, the knee is flexed in the prone patient. With the Cincinnati incision, the surgeon is looking at the planter aspect of the foot and through the incision and up the calf.
- The Achilles tendon is lengthened in a notch fashion.
- The medial half of the Achilles insertion is released to reduce the varus force. Fibrotic bands and tendon sheath should also be released.
- If the Achilles lengthening is not sufficient to restore the anatomy, the posterior aspects of the subtalar and ankle joints are sequentially released.
- The first step is to identify and protect the sural nerve and vessels laterally and the posterior tibial neurovascular bundle medially. The flexor hallucis is then identified posteromedially and protected. The peroneal tendons are also identified and protected (TECH FIG 4).
- The ankle capsule is noted and incised from the postero-medial to the posterolateral corners to allow dorsiflexion of the talus in the mortise.

MEDIAL SOFT TISSUE RELEASE

- Medial release is undertaken if the posterior release as described above does not correct the anatomy.
- First, the posterior portion of the Cincinnati incision is extended medially to the medial aspect of the navicular.
- The posterior tibial neurovascular bundle is protected while releasing any thickened fascia as well as the flexor hallucis, which may have been lengthened through the posterior part of the incision.
- The posterior tibial tendon is located just distal to the flexor digitorum tendon and is lengthened in notch fashion as necessary.
- The abductor hallucis muscle is lengthened proximally or distally. The flexor digitorum tendon is identified just anterior to the posterior tibial neurovascular bundle and lengthened in notch fashion as necessary (TECH FIG 5).
- Deciding whether to lengthen the anterior tibialis tendon can be difficult. If the anterior tibialis tendon appears contracted on anatomic correction, it should be lengthened in a Z-lengthening. Occasionally, the anterior tibialis tendon remains overactive and will need to be lengthened at a future time.
- A helpful hint for the lengthening of the tendons on the medial side of the foot: Each of the ends of the lengthened tendons should be tagged with suture, which is then held in a color-coded bulldog clamp. Each group of the proximal and distal sets of clamps can then be held in proper order by a safety pin. This will avoid confusion when it is time to repair the tendons after anatomic realignment of the foot is accomplished.
- Release of the plantar fascia has been recommended in the past but is currently avoided since it can contribute to later pes planovalgus. Do not release the plantar fascia in cases of rocker-bottom deformity during the casting.
- Care should be taken to avoid injury to the medial plantar vessels and nerve.
- If lengthening of these tendons does not permit anatomic alignment, follow this addendum:
  - Identify and release the talonavicular joint. The navicular is medially displaced on the talonavicular joint, making

The subtalar joint is found and incised posteriorly, then medially and laterally to the interosseous ligament. The fibulotalar and fibulocalcaneal ligaments can be released as needed.

This release should allow the ankle joint to dorsiflex at least 20 degrees. If the hallux is tightly flexed, the flexor hallucis can be lengthened through this incision by Z-lengthening.
the talonavicular joint obliquely, rather than transversely, oriented.

- Follow the distal stump of the notch-lengthened posterior tibial tendon to its insertion on the navicular.
- The capsule is released medially, plantarly, and dorsally and as far laterally as can be reached safely. Be careful not to cut the talar neck, as this may lead to avascular necrosis or growth disturbances!
- Release the subtalar capsule from the talonavicular joint to the interosseous ligament medially, including the spring ligament. Be careful not to damage the deep deltoid ligament. A Freer elevator placed into the ankle joint posteriorly can help identify the ankle and subtalar joints.
- Reach the medial aspect of the calcaneocuboid joint by carefully dissecting the soft tissues from the plantar aspect of the talus neck. Release of this capsule will allow a wedge opening of the calcaneocuboid joint to straighten the lateral column. Another landmark to the calcaneocuboid joint from the medial side of the foot is the peroneus longus tendon crossing from lateral to plantar.
- Many authors have described release of the interosseous ligament through this incision. It is important to preserve this ligament as a pivot axis and to preserve its associated blood supply to the talus.

**LATERAL SOFT TISSUE RELEASE**

- A problem often occurs when the calcaneus has rotated under the talus on the interosseous membrane and is tethered by a stiff, fibrotic lateral capsule. If the above posterior and medial releases do not permit anatomic alignment, a lateral release may be needed.
- The posterior portion of the Cincinnati incision, made for the posterior release, is extended laterally at the level of the subtalar joint to the talonavicular joint.
- The extensor digitorum brevis is identified over the sinus tarsi. Its plantar edge is divided from the lateral calcaneus and the muscle is elevated to expose the sinus tarsi and neck and head of the talus.
- The lateral capsule of the talonavicular joint is exposed and released. A circumferential release of the talonavicular joint is thus completed (TECH FIG 6).
- The beak of the calcaneus is then palpated. From the lateral aspect of the talonavicular joint, cut the lateral subtalar capsule, between the beak of the calcaneus and the talar neck, proximally to the interosseous ligament, completing circumferential release of the subtalar capsule.

**REALIGNMENT OF THE BONES OF THE FOOT**

- Once the appropriate soft tissues have been released, the foot can be realigned.
- A finger is placed over the talar head dorsolaterally while the foot is laterally rotated in slight supination. This is similar to the Ponseti manipulation.
- A Freer elevator can be placed in the ankle joint in line with the dome of the talus (axis of the talus). The foot should be rotated until the first metatarsal is just lateral to the talar dome axis.
- This maneuver should correct the lateral border to straight and the heel into slight valgus and reduce the talar head under the navicular (the navicular should be slightly proud to palpation as in normal feet), without wedging open the subtalar joint (TECH FIG 7).
FIXATION

- Holding the foot in the anatomically corrected position until the capsules and tendons heal is best done with a 0.062-inch Kirschner wire, which is passed from the posteromedial talus through the center of the head and into the navicular and the medial cuneiform and out the first web space (TECH FIG 8A).
- Intraoperative radiographic images should be obtained at this point to confirm that all components of the reduction have been obtained (TECH FIG 8B,C).
- All of the joints should be congruous. Wedged-open joints may indicate incomplete release of bone deformity, requiring osteotomy.
- Proper reduction should result in near-normal motion of the ankle. The fixation pin restricts the foot motion.
- If division of the interosseous ligament (rarely needed in my experience) has been performed, a second pin should be placed from the calcaneus into the talus to maintain the alignment of the subtalar joint.

REPAIR OF TENDONS

- Once the foot is anatomically aligned, the tendons are repaired with the foot at 90 degrees to the tibia.
- Do not repair the tendons until the bones have been realigned anatomically. Repairing the tendons at too short a length will result in rapid recurrence.
- Capsules and ligaments should not be repaired surgically. They will heal.
# POSTOPERATIVE CARE

- During the first postoperative week, a Jones-type dressing is preferred to allow for swelling in children under 6 months of age. Bulky dressings and casts are recommended for children over 6 months.
- Ponseti-type casting will help maintain the alignment. Casts should be changed at 1 week and continue for 3 months.
- Braces are helpful for prolonged periods, if recurrence occurs or underlying neuromuscular disease has been identified.
- After incisions, wound closure and positioning in equinus for 2 weeks allows healing and can be followed by serial casting to stretch the soft tissues to dorsiflex the ankle.
- Pins may be removed after 4 to 6 weeks.
- Muscle balancing is better left for a later time, after rehabilitation from extensive surgical release.

# OUTCOMES

- As noted previously, surgery is usually necessary only with the most resistant forms of clubfoot.
- Successful results can be obtained in 52% to 91% of cases, enabling most children to participate in normal activities.\(^4\)
- Stiffness, recurrence, and weakness are common, and no treatment known today can correct the underlying neuromuscular causes.
- The incidence of a poor outcome is higher in children who have surgery before 6 months of age. Waiting to treat young patients may be beneficial since it allows for growth of the anatomy as well as time to fully evaluate the case.\(^3\)
- These children should be referred to centers with the most experience.

# COMPLICATIONS

- The challenges that this deformity presents ultimately may lead to a variety of complications:\(^3\):
  - Skin slough and wound dehiscence
  - Neurovascular complication
  - Physeal damage
  - Osteonecrosis of the talus
  - Aseptic necrosis of the navicular
  - Failure to achieve or loss of correction
  - Overcorrection or undercorrection
  - Hindfoot valgus
  - Forefoot abduction or adduction
  - Calcaneus deformity
  - Pes planus
  - Persistent equinus
  - Heel varus
  - Dorsal forefoot subluxation with apparent cavus
  - Skew foot
  - Dorsal bunion
  - Claw toes
  - Anesthetic foot
  - Sinus tarsi syndrome
  - Restricted motion
  - Reduced calf girth and foot size
  - Recurrence of the deformity
  - Neuromuscular abnormalities, growth disturbances, and simple muscular or mechanical imbalance can lead to recurrence or overcorrection throughout the growth period. Stretching, bracing, casting, and even additional surgery may be needed.

# REFERENCES

DEFINITION
- The incidence of residual deformity in congenital clubfoot ranges from 26.6% to 50%, regardless of the initial treatment provided.²
  - The disparity in the reported incidence is due to varying severity of clubfoot deformity, different methods of treatment, and, in part, differing definitions of residual deformity.
- Residual deformities include isolated equinus, cavus, metatarsus adductus, forefoot supination, and combinations of the above.
- Dynamic forefoot adduction and supination can be observed after clubfoot treatment with or without soft tissue releases.
- Dynamic forefoot supination deformity results from residual medial displacement of the navicular on the head of the talus, which results in muscle imbalance. In this case, because its insertion is medially displaced, the anterior tibialis becomes a forefoot supinator instead of a dorsiflexor. In addition, deformity may also occur because the anterior tibialis muscle is relatively strong in comparison to the peroneal muscles (FIG 1).
- The aim of treatment is to correct any fixed deformity and to rebalance the muscles of the foot, thereby correcting dynamic deformity and improving foot alignment.

ANATOMY
- The anterior tibialis muscle originates from the upper two thirds of the tibia.
  - The anterior tibialis tendon fibers rotate 90 degrees from the musculotendinous junction to its insertion on the medial cuneiform and first metatarsal.
  - Medial rotation begins proximally, so the most medial muscle fibers proximally rotate to the posterior surface of the tendon near the midpoint and continue to rotate so that their final insertion is as the distal–lateral fibers on the first metatarsal.
- Meanwhile, the most lateral muscle fibers proximally rotate to the anterior surface at the midpoint and continue distally to insert on the cuneiform as the proximal–medial fibers (FIG 2).⁴
- The anterior tibialis muscle is active in two important stages of the gait cycle; it concentrically fires during the initiation of swing phase and keeps the foot dorsiflexed during early swing phase and then it relaxes.
- The anterior tibialis muscle then fires eccentrically as the foot is lowered to the floor from heel strike to foot flat in stance phase.
- As a dorsiflexor, the anterior tibialis muscle opposes gravity and the strong gastrosoleus complex. Importantly, the anterior

---

FIG 1 • Normal foot versus supinated foot. Medial subluxation of the navicular, the medial cuneiform, and the first metatarsal results in supination deformity as the line of pull of the tibialis anterior tendon directs the foot into supination instead of dorsiflexion.

FIG 2 • Anatomy of the tibialis anterior muscle-tendon. The anterior tibialis tendon fibers rotate 90 degrees from their musculotendinous junction to their insertion on the medial cuneiform and the first metatarsal such that the proximal-medial insertional fibers on the cuneiform begin as the lateral fibers at the musculotendinous junction (see window).
tibialis muscle may also be a supinator of the forefoot in the face of peroneal longus weakness or medial displacement of the insertion.

There are important bony abnormalities associated with residual clubfoot deformity.

- The subtalar joint may have an absent anterior facet and small, narrow medial and posterior facets, resulting in restricted subtalar motion. In this setting, the calcaneus does not slide fully into valgus with casting such that the navicular remains medially displaced.
- The navicular itself is wedge-shaped and is medially displaced along with the cuneiforms and metatarsals. With medial displacement of its insertion, the biomechanical advantage favors the action of the anterior tibialis muscle as a strong supinator over its role as a dorsiflexor (FIG 3).

PATHOGENESIS

- The cause of residual clubfoot deformity may be incomplete correction or recurrence of deformity as part of the natural history of the resistant clubfoot.
- Electromyographic studies have demonstrated that the peroneal muscle group can be relatively weaker, thus increasing the supinator action of the tibialis anterior muscle. The navicular malleolar distance demonstrates the extent of medial displacement of the navicular. The navicular–medial malleolar distance is decreased compared to the normal foot. In fact, the medial malleolus can be difficult to quantify as midfoot breech will often accommodate and hide the hindfoot equinus (FIG 4).
- Correction of resistant congenital clubfoot often requires more than one surgery, not because of a “failed initial intervention,” but because of dynamic muscle imbalances that may not be fully manifest at the time of the initial intervention. Thus, the need for an additional operation can be perceived as part of the natural history of congenital clubfoot. If left untreated, the dynamic deformity may become stiff and the foot tends to invert. When inversion deformity is combined with residual equinus deformity, hindfoot varus may recur (FIG 4).

PATIENT HISTORY AND PHYSICAL FINDINGS

- Residual deformity is more likely in patients who have clubfoot as a result of myelomenigocele or other neuromuscular syndromes and genetic disorders such as Larsen syndrome. Therefore, it is important to consider neurologic causes, such as tethered cord, when confronted with residual deformity. Recurrent deformity may be found in children with only four toes on the affected foot, as these individuals may have absence of the peroneal muscle group (similar to that seen in fibular hemimelia), thus leaving them prone to recurrence.
- One of the first clinical signs of recurrence is a dynamic inversion of the foot with slight equinus. Equinus may be difficult to quantify as midfoot breech will often accommodate and hide the hindfoot equinus (FIG 5).
- Residual deformity most frequently occurs in severe or atypical cases, which are often associated with a small calf size. These children may also have short, fat feet with a deep planter crease that extends from the medial border to the lateral border of the foot and a shortened first ray. These findings are consistent with severe or atypical clubfeet that have a propensity for residual deformity.
- In maximum pronation or maximum supination, the navicular–medial malleolar distance is decreased compared to the normal foot. In fact, the medial malleolus can be difficult to delineate because it is in contact with the navicular. The navicular malleolar distance demonstrates the extent of medial subluxation.
- It is important to examine gait when possible. During examination of gait, the clinician should identify whether the tibialis anterior is a dynamic supinator; this is best observed in swing phase when no antagonist muscles contract. This finding will confirm the appropriateness of surgery.

NATURAL HISTORY

- Residual deformities are usually encountered within the first year after initial treatment and generally before the age of 5 years, even in congenital clubfeet that had been fully corrected since the first month of life.
- Residual forefoot adduction and supination are the most common deformities after nonoperative treatment and can also be seen after initial operative repair. They can result from undercorrection at the time of the primary intervention.

- Correction of resistant congenital clubfoot often requires more than one surgery, not because of a “failed initial intervention,” but because of dynamic muscle imbalances that may not be fully manifest at the time of the initial intervention. Thus, the need for an additional operation can be perceived as part of the natural history of congenital clubfoot. If left untreated, the dynamic deformity may become stiff and the foot tends to invert. When inversion deformity is combined with residual equinus deformity, hindfoot varus may recur (FIG 4).

FINDINGS

- Correction of resistant congenital clubfoot often requires more than one surgery, not because of a “failed initial intervention,” but because of dynamic muscle imbalances that may not be fully manifest at the time of the initial intervention. Thus, the need for an additional operation can be perceived as part of the natural history of congenital clubfoot. If left untreated, the dynamic deformity may become stiff and the foot tends to invert. When inversion deformity is combined with residual equinus deformity, hindfoot varus may recur (FIG 4).

FIG 3 • Bony abnormalities associated with residual clubfoot deformity. The navicular is wedge-shaped and is medially displaced along with the cuneiforms and metatarsals.
The strength of the tibialis anterior is tested. With dynamic supination deformity, the supinator action of the anterior tibialis muscle will overpower the dorsiflexor action, thus demonstrating the appropriateness of surgery. In addition, good power is needed for a successful transfer.

Range of motion of the ankle is examined. Transfer will work only as long as there is not a fixed contracture.

The clinician should evaluate for other deformities, such as equinus, cavus, varus, adductus, and tibial torsion.

**IMAGING AND OTHER DIAGNOSTIC STUDIES**

Anteroposterior (AP) and lateral radiographs may be helpful to study and quantify various deformities.

AP radiographs will demonstrate medial deviation of the metatarsals, which can indicate residual medial displacement of navicular, which is yet to ossify (FIG 6).

- On an AP radiograph of normal feet, the line drawn through the long axis of the talus should point to the first metatarsal, while the line drawn through the long axis of the calcaneus should point toward the fourth metatarsal.
- In clubfeet, these lines become more parallel, depicting “stacking” of the talus and calcaneus.
- Forced maximum dorsiflexion lateral radiographs may reveal hindfoot equinus with midfoot breech.
- Stacking of the metatarsals on the lateral radiograph identifies the presence of residual forefoot supination (a decreased talocalcaneal angle).
Ultrasound evaluation of the foot is not done routinely. However, experimental studies have demonstrated that this technique is capable of documenting the location of the navicular in relationship to the head of the talus. The navicular is subluxated plantarward and medially on the head of the talus.

Similarly, magnetic resonance imaging can be performed to completely identify the relationships of the cartilaginous bones. Although possible, this technology is rarely clinically used as orthopaedists are aware of the classic deformities that are associated with recurrence.

DIFFERENTIAL DIAGNOSIS

Residual deformities in clubfoot may be due to unrecognized tarsal coalitions or other conditions in severe or atypical feet.

Unexpected and rapid recurrent deformity in children with previously corrected feet and with known myelomeningocele may be a result of continued neurologic involvement, such as tethering of the spinal cord.

NONOPERATIVE MANAGEMENT

Treatment of residual deformity depends on the location, severity, and age of the child.

Recasting may be considered in children less than 18 months of age who have residual deformity.

Most residual deformities at this age can be treated by Ponseti manipulation, followed by application of a toe-to-groin plaster cast with the feet in a fully corrected position for 2 weeks.

After 2 weeks, the casts are removed and reapplied.

Usually three casting sessions are required, for a total of 6 weeks.

Thereafter, abduction bracing is reinstituted.

In larger children, ankle–foot orthoses (AFOs) may also be used to prevent recurrence.

Physiotherapy may also be used in patients with residual deformity. The therapist must be familiar with techniques to manipulate residual forefoot adductus and posterior contracture.

In older children and in patients with midfoot breech, it can be difficult to effectively stretch any hindfoot equinus contracture.

With equinus contracture, abduction bracing is difficult.

Unbraceable posterior contracture can then lead to recurrent metatarsus adductus and forefoot supination. Thus, a repeat percutaneous heel cord tenotomy and casting may be required.

SURGICAL MANAGEMENT

In children more than 2 to 3 years of age, it may be preferable to correct any residual deformity using soft tissue lengthenings or transfers with or without bony procedures.

As the anterior tibialis acts as a supinator, lateral transfer of the anterior tibialis tendon is often necessary to correct dynamic supination deformity.

The optimal age for lateral transfer of the anterior tibialis tendon varies from case to case.

Important factors are the rapidity of recurrence, the strength of the anterior tibialis muscle, the presence of fixed forefoot deformity, or the presence of concurrent equinus deformity or cavus.

The surgery should be performed after the lateral cuneiform ossification center appears (2 to 4 years of age). The split anterior tibialis tendon transfer (SPLATT) of Hoffer is rarely used in idiopathic clubfeet but is an excellent method for correcting dynamic supination deformity as a result of spasticity associated with disorders such as cerebral palsy.

This method may have some utility in children with mild, flexible forefoot supination who require surgery for other deformity.

Preoperative Planning

Feet with residual deformity should be extensively evaluated by clinical and radiographic assessment before surgical planning. Each foot should be treated individually, as no single treatment plan is appropriate for all feet.

Associated deformities must be identified. For example, an anterior tibialis transfer will function poorly in the face of a fixed equinus contracture. In this case, it will be necessary to correct equinus deformity with a heel cord tenotomy or lengthening or posterior release.

Residual varus deformity may indicate the need for an opening wedge or sliding calcaneal osteotomy.

Persistent metatarsals adductus may necessitate midfoot osteotomies in order for the lateral border of the foot to be reduced.

Anterior tibialis tendon transfer does not correct restricted subtalar motion.

It is important to confirm that the ossific nucleus of the lateral cuneiform is present in order to place the anterior tibialis tendon into an appropriate anchor site.

Positioning

The patient is placed in the supine position on a standard operating table or a hand table.

Either positioning is done in a way to ensure good fluoroscopic images.

A well-padded thigh-high tourniquet should be placed before preparing and draping the patient.

Approach

A medial incision is based over the insertion of the anterior tibialis tendon.

From this incision the surgeon may be able to perform an opening wedge osteotomy of the medial cuneiform if indicated.

Once the anterior tibialis tendon is detached, a lateral incision is based over the lateral cuneiform.

Fluoroscopic imaging can assist in planning this incision.

The lateral incision may need to be longer and more laterally based should the surgeon decide to perform a cuboid closing wedge osteotomy at the same time.
FULL ANTERIOR TIBIALIS TENDON TRANSFER TO THE LATERAL CUNEIFORM: MODIFIED GARCEAU TECHNIQUE\textsuperscript{5,11}

Approach
- A 4-cm-long dorsal-medial longitudinal skin incision is made over the course of the anterior tibialis tendon from the inferior margin of the ankle retinaculum (the superior limb of the inferior extensor retinaculum) to its palpable distal insertion based over the medial cuneiform (TECH FIG 1).
- Dissection is carried down through subcutaneous tissues and the inferior limb of the inferior extensor retinaculum to expose the tendon sheath.
  - The anterior tibialis tendon sheath is incised sharply and opened as far distally as possible and then proximally to just short of the ankle retinaculum.
- A hemostat is placed under the anterior tibialis tendon to help expose the insertion.
- This broad extensive insertion is detached as far distally as possible to gain maximum length of tendon for the transfer.
  - It is critical to obtain as much length as possible.

Transferring the Tendon
- Once the tendon is freed and detached distally, a strong absorbable suture (eg, 1-0 Vicryl) is woven in a Bunnell-type fashion through the anterior tibialis tendon.
  - Care is taken to weave the suture in a fashion that does not lead to a bulbous end, thus making the tendon difficult to deliver to the lateral wound and subsequently pass into the lateral cuneiform.
  - Occasionally, the loose ends of the tendon insertion are trimmed or incorporated with a 3-0 absorbable suture to facilitate passage and anchoring.
- By pulling on the suture, the tendon is gently pulled distally while the soft tissue attachments to the tendon are freed up to, but not beyond, the ankle retinaculum.
  - To avoid bowstringing of the tendon, it is important not to release the ankle retinaculum.
  - A dorsal-lateral longitudinal incision, 1.5 to 2 cm long, is made over the lateral cuneiform.
  - The lateral cuneiform is identified just proximal to the base of the third metatarsal.
  - Dissection is carried down through subcutaneous tissues to the toe extensors.
  - To expose the lateral cuneiform, the toe extensors are retracted medially and the extensor digitorum brevis muscle is retracted laterally.
  - A cruciate periosteal incision is made directly over the lateral cuneiform, carefully avoiding the adjacent joint articulations.
  - In young children, a Keith needle is used to fluoroscopically locate the center of the ossific nucleus.
  - In older children, a small periosteal elevator is used to elevate the periosteal flaps off the lateral cuneiform.
  - Occasionally, these flaps may be sutured into the transferred tendon, thus supplementing fixation. In young children, however, it may be difficult and futile to elevate perichondrium from the predominantly cartilaginous bone.
  - A blunt hemostat is then passed from the lateral incision over the lateral cuneiform and under the extensor tendons to the point where the anterior tibialis tendon passes beneath the ankle retinaculum.
  - Use the hemostat to develop a tract for the transfer of the anterior tibialis tendon.
  - The hemostat is passed into this same tract into the medial wound to grasp the suture ends and bring the anterior tibialis tendon into the lateral cuneiform (TECH FIG 2).
  - Ensure that the available length of the tendon will reach the proposed transfer site into the lateral cuneiform.
Attaching the Transferred Tendon

- A drill bit is selected to be slightly larger than the diameter of the sutured anterior tibialis tendon end.
  - Once the bit is selected, make a hole directly in the center of the lateral cuneiform, drilling just through the plantar aspect of the bone (dorsal to plantar while aiming for the arch of the foot).
- The suture ends of the tendon are threaded onto Keith needles (TECH FIG 3A).
- While the foot is maximally dorsiflexed and everted, the suture needles are passed through the lateral cuneiform drill hole and out through the plantar aspect of the foot, guiding the tendon through the drill hole.
- The tendon is confirmed to easily and reproducibly slide into its new insertion.
  - This is a critical step: be certain that the tendon reliably enters the anchoring hole after the skin is closed when the foot is dorsiflexed and when the suture is tensioned.
- The suture needles on the plantar aspect of the foot are passed through a nonadhesive dressing (eg, Adaptic) and a sterile felt pad.
- At this time it is advisable to irrigate and close all other associated wounds, leaving the lateral recipient wound for last.
  - This way the surgeon can ensure that the anterior tibialis is in the intended position just before dressing and cast application.
- The periosteum of the lateral cuneiform is sutured with two interrupted absorbable sutures to the transferred anterior tibialis tendon while it is pulled into the recipient site (TECH FIG 3B).
- The lateral wound is irrigated and closed in layers while the foot is held in a dorsiflexed position, thus ensuring that the anterior tibialis remains in the hole and the continuity of the periosteal sutures is preserved.
- Sterile dressings are applied while an assistant simultaneously maintains the foot dorsiflexed with tension on the suture.
- The distal foot and ankle portion of a toe-to-groin cast is applied, while ensuring that the suture ends of the tendon are in tension.
- In the past we have tied the button over the felt underneath the cast. However, a high rate of pressure sores has led us to consider alternative fixation.
  - After the cast is hardened, the suture is tied over a button on the exterior of the plantar aspect of the cast (TECH FIG 3C).
  - To prevent plantar pressure sores, make sure the plaster is sufficiently hardened.
- Some surgeons will perform the exact procedure except transfer the whole tendon into the cuboid. These surgeons choose this insertion site if the foot has a concurrent fixed forefoot deformity and mild hindfoot varus that they choose not to correct.
  - We prefer to correct the fixed deformity and transfer the anterior tibialis into the lateral cuneiform as we fear overcorrection from the more lateral insertion into the cuboid.
- Some surgeons add a third incision at the anterior distal tibia directly over the anterior tibialis tendon and just lateral to the tibial crest. The tendon can be easily palpated. The tendon sheath is incised here and the freed distal tendon end is pulled with a hemostat into this incision. From this incision, the freed distal tendon end is eventually pulled into the lateral incision for attachment.
Tech FIG 3 • A. The suture ends of the tibialis anterior tendon are threaded onto Keith needles and passed into the drill hole through the plantar aspect of the foot. The tendon is guided into the drill hole. B. While the foot is maximally dorsiflexed and everted, the tendon is secured.

C. The cast is molded and hardened with the foot in dorsiflexion and eversion and with the suture ends under appropriate tension. The suture is tied over a button on the exterior of the hardened cast to prevent plantar pressure sores.

### SPLIT ANTERIOR TIBIALIS TENDON TRANSFER (SPLATT)

**Approach**
- A 4-cm-long dorsal-medial skin incision is made over the course of the anterior tibialis tendon from the inferior margin of the ankle retinaculum (the superior limb of the inferior extensor retinaculum) to its palpable distal insertion based over the medial cuneiform.
- Dissection is carried down through subcutaneous tissues and the inferior limb of the inferior extensor retinaculum to expose the tendon sheath.
  - The anterior tibialis tendon sheath is incised sharply and opened as far distally as possible and then proximally to just short of the ankle retinaculum.
  - The lateral half of the anterior tibialis tendon insertion is detached as far distally as possible to gain maximum length of tendon for the transfer.
  - A strong absorbable suture (eg, 1-0 Vicryl) is woven in a Bunnell-type fashion through the lateral half of the anterior tibialis tendon.

**Transferring the Tendon**
- The suture is grasped and pulled, allowing the lateral tendon to be gently dissected proximally but not beyond the ankle retinaculum.
  - To avoid bowstringing of the tendon, it is important not to release the ankle retinaculum.
- A dorsal-lateral longitudinal incision, 1.5 to 2 cm long, is made over the cuboid in line with the fourth metatarsal axis.
- Dissection is carried down through subcutaneous tissues to the toe extensors.
  - To expose the cuboid, the toe extensors are retracted medially.
  - A cruciate periosteal incision is made directly over the cuboid, carefully avoiding the adjacent joint articulations.
  - An appropriate drill hole is then made in the cuboid, drilling dorsal to plantar in line with the fourth metatarsal axis and through the plantar aspect of the bone.
PEARLS AND PITFALLS

**Indications**
- Anterior tibialis transfer will work only as long as there is not a fixed contracture. Flexibility of the foot is the main condition for a successful surgical result, because the surgical procedure is based on the dynamic muscle imbalance of the forefoot.

**Positioning**
- Use of a tourniquet at 200 to 250 mm Hg will allow easier surgery.

**Tendon harvest**
- Too short a tendon can make transfer difficult, so the surgeon should obtain as much length as possible.
- Bowstringing and weakness by inadvertently cutting the extensor retinaculum should be avoided.
- The surgeon should attach a suture to the released tendon to allow ease of handling and passing. This will also keep the tendon from fraying as it exits the donor site.

**Tendon fixation**
- It may be difficult to locate the lateral cuneiform in small children. Therefore, intraoperative fluoroscopy should be available.
- An absorbable suture is used to hold the tendon as it usually dissolves and weakens by 6 weeks.
- Alternative forms of fixation may be considered in older children with large bones, such as a suture anchor (FIG 7).
- Overcorrection can be avoided with insertion of the full tendon transfer along the third metatarsal axis. For the split tendon transfer, the optimal site for insertion to obtain maximal dorsiflexion in biomechanical studies is along the fourth metatarsal axis.9

**Wound closure**
- All wounds are closed except the recipient site to be sure that the transferred tendon stays in the tunnel. Also, the foot is kept in maximum dorsiflexion during final wound closure and casting. A well-trained assistant is paramount.

**Cast management**
- Pressure sores on the bottom of the foot can result from too much tension on the button. Therefore, it should be placed on the exterior of the cast.
- Swelling and pressure sores may result if extensive and lengthy procedures are done. In these cases, prophylactic dorsal splitting of the cast in the operating room is important.
POSTOPERATIVE CARE

- In patients under 5 years of age and those who may be non-compliant, a toe-to-groin bent-knee cast is maintained with the patient non-weight bearing for about 6 weeks.
  - At 6 weeks, the button and suture are removed and the patient is allowed to begin walking.
- In older children, a short-leg cast for an initial 6 weeks is maintained.
  - At 6 weeks, the button is removed and patient is placed in a short-leg walking cast for an additional 3 weeks to ensure healing and to avoid tendon rupture.
- Clinical and radiographic assessment of outcomes is performed at the end of healing. Plain radiographs (standing AP and lateral foot radiographs) are usually sufficient. CT examination may be obtained if indicated (FIG 8).

OUTCOMES

- Successful surgery will be noted by correction of the supination deformity and conversion of the anterior tibialis into the primary dorsiflexor of the foot. Clinical examination of the foot during active dorsiflexion demonstrates the new insertion site of the anterior tibialis tendon.
- Twenty-seven previously treated clubfeet in 25 patients were retrospectively evaluated after tibialis anterior tendon transfer to correct residual dynamic supination deformity.\(^1\) All showed active contraction of the transferred tibialis anterior tendon. There was no case of overcorrection.
- Clinical and radiographic improvement in both forefoot abduction and supination was demonstrated in 71 cases of residual dynamic congenital clubfoot deformity treated by full and split anterior tendon transfer, with an increase in the eversion strength of the tibialis anterior muscle.\(^8\)
- Farsetti et al\(^2\) confirmed the findings of multiple studies, demonstrating that transfer of the anterior tibial tendon to the lateral cuneiform underneath the extensor retinaculum corrects and stabilizes relapsing clubfeet by restoring normal function of foot dorsiflexion–eversion. In their two series of patients reviewed at the end of skeletal growth, none of the operated patients had further relapse.

COMPLICATIONS

- Undercorrection
- Cast sores
- Wound infection
- Loosening of the transferred tendon
- Rupture of the transferred tendon
- Bowstring at the anterior ankle joint resulting in weakness and a cosmetic deformity
- Loss of dorsiflexion force
- Overcorrection

OVERVIEW

- An understanding of the basic biology and pathology of bone and soft tissue tumors is essential for appropriate planning of their treatment.
- This chapter reviews the unique biologic behavior of soft tissue and bone sarcomas, which provides the basis for their staging and resection and the use of appropriate adjuvant treatment modalities.
- A detailed description of the clinical, radiographic, and pathological characteristics for the most common sarcomas is presented.

EPIDEMIOLOGY

- Soft tissue and bone sarcomas are a rare and heterogeneous group of tumors. These neoplasms represent less than 1% of all adult and 15% of pediatric malignancies.
- As of 2006, the annual incidence in the United States, which remains relatively constant, was approximately 6000 to 7000 soft tissue sarcomas and 2750 bone sarcomas.
- In 2006, the overall mortality rate was 30% for soft tissue sarcomas and 45% for bone sarcomas.
- In the U.S., the 5-year survival rates for osteosarcoma and Ewing sarcoma were comparable among 15- to 29-year-olds, about 60% for the most recent era. Survival rates for chondrosarcoma exceeded 90% in the most recent era. The U.S. bone cancer mortality was highest for males and females 15 to 19 years of age.

RISK FACTORS

- Risk factors for soft tissue and bone sarcomas include previous radiation therapy, exposure to chemicals (eg, vinyl chloride, arsenic), immunodeficiency, prior injury (scars, burns), chronic tissue irritation (foreign body implants, lymphedema, chronic infection), neurofibromatosis, Paget disease, bone infa�数, and genetic cancer syndromes (eg, hereditary retinoblastoma, Li-Fraumeni syndrome, Gardner syndrome, Rothmund–Thomson syndrome, Werner syndrome, Bloom syndrome, Marfucci syndrome, Ollier disease, multiple osteochondromatosis, and hereditary multiple exostoses. In most patients, however, no specific etiology can be identified.
- In the past two decades, both survival and quality of life of patients with soft tissue and bone sarcomas have improved dramatically as a result of the multimodality treatment approach. Limb-sparing surgery, used in combination with chemotherapy and radiation therapy, can achieve cure in the majority of patients with soft tissue and bone sarcomas, and resection is performed in lieu of amputation in more than 90% of all patients.
- The three most common soft tissue sarcomas are malignant fibrous histiocytoma (MFH), liposarcoma, and leiomyosarcoma.
- The most common bone sarcomas are osteosarcoma, chondrosarcoma, and Ewing sarcoma.

PATHOPHYSIOLOGY AND BIOLOGIC BEHAVIOR

- Sarcomas originate primarily from elements of the mesodermal embryonic layer.
- Soft tissue sarcomas are classified according to the adult tissue that they resemble.
- Similarly, bone sarcomas usually are classified according to the type of matrix production: osteoid-producing sarcomas are classified as osteosarcomas, and chondroid-producing sarcomas are classified as chondrosarcomas.
- Tumors arising in bone and soft tissues have characteristic patterns of biologic behavior because of their common mesenchymal origin and anatomic environment. Those unique patterns form the basis of the staging system and current treatment strategies.
- Histologically, sarcomas are graded as low, intermediate, or high grade. The grade is based on tumor morphology, extent of pleomorphism, atypia, mitosis, matrix production, and necrosis, with the two main factors being mitotic count and spontaneous tumor necrosis.
- Tumor grade represents the tumor’s biologic aggressiveness and correlates with the likelihood of metastases. Low-grade lesions metastasize in fewer than 15% of patients. High-grade lesions metastasize in over 20% of patients.
- Sarcomas form a solid mass that grows centrifugally, with the periphery of the lesion being the least mature.
- In contradistinction to the true capsule that surrounds benign lesions, which is composed of compressed normal cells, sarcomas usually are enclosed by a reactive zone, or pseudocapsule. This pseudocapsule consists of compressed tumor cells and a fibrovascular zone of reactive tissue with a variable inflammatory component that interacts with the surrounding normal tissues.
- The thickness of the reactive zone varies according to the histogenic type and grade of malignancy. High-grade sarcomas have a poorly defined reactive zone that may be locally invaded by the tumor (FIG 1A).
- Tumor foci within the reactive zone are called satellite lesions.
- High-grade, and occasionally low-grade, may break through the pseudocapsule to form metastases, termed skip metastases, within the same anatomic compartment in which the lesion is located. By definition, these are locoregional micrometastases that have not passed through the circulation (FIG 1B).
- This phenomenon may be responsible for local recurrences that develop in spite of apparently negative margins after a resection.
- Although low-grade sarcomas regularly interdigitate into the reactive zone, they rarely form tumor skip nodules beyond that area (FIG 1C,D).
- Sarcomas respect anatomic borders. Local anatomy influences tumor growth by setting natural barriers to extension. In
Unique features are formation of reactive zone, intracompartmental growth, and, rarely, the presence of skip metastases. Skip nodules are tumor foci not in continuity with the main tumor mass that form outside the pseudocapsule. "Satellite" nodules, by contrast, form within the pseudocapsule. D. Gross specimen. Skip metastases (arrows) from an osteosarcoma of the distal femur. This finding is documented preoperatively in less than 5% of patients. E. Sagittal section of a high-grade osteosarcoma of the distal femur. The growth plate, although not invaded by the tumor in this case, is not considered an anatomic barrier to tumor extension, probably because of the numerous vascular channels that pass through the growth plate to the epiphysis. However, the articular cartilage is an anatomic barrier to tumor extension and very rarely is directly violated by a tumor. F. Coronal section of a high-grade osteosarcoma of the distal femur. Although gross involvement of the epiphysis and medial cortical breakthrough and soft tissue extension are evident, the articular cartilage is intact. This phenomenon allows intra-articular resection of high-grade sarcomas of the distal femur in most cases. Thick fascial planes are barriers to tumor extension. G. Axial MRI, showing a high-grade leiomyosarcoma of the vastus lateralis and vastus intermedius muscles. The tumor does not penetrate, looking in a clockwise direction, the lateral intermuscular septum, the adductor compartment, and the aponeuroses of the sartorius and rectus femoris muscles. (Courtesy of Martin M. Malawer.)
general, sarcomas take the path of least resistance and initially
grow within the anatomic compartment in which they arose.
It is only at a later stage that the walls of the compartment are
violated (either the cortex of a bone or aponeurosis of a
muscle), at which time the tumor breaks into a surrounding
compartment.

- Typical anatomic barriers are articular cartilage, cortical
bone, and fascial borders. The growth plate is not consid-
ered an anatomic barrier, because it has numerous vascu-
lar channels that run through it to the epiphysis (FIG
1E–G).

- Sarcomas are defined as intracompartmental if they are en-
cased within an anatomic compartment.
- Extracompartmental tumors are those that grow out
through the compartment barrier or tumors that have arisen
in extracompartmental spaces (space tumors), ie, popliteal
fossa, groin, sartorial canal, axilla, and antecubital fossa
(FIG 2A,B).
- Most bone sarcomas are bicompartamental at the time of
presentation; they destroy the overlying cortex and extend di-
rectly into the adjacent soft tissues.
- Carcinomas, which typically present in the extremities as
metastatic disease, directly invade the surrounding tissues, ir-
respective of compartmental borders (FIG 2C–E).

- Joint involvement in sarcoma is uncommon, because direct
 tumor extension through the articular cartilage is rare.
Mechanisms of joint involvement in sarcoma are as follows:
- Pathological fracture with seeding of the joint cavity
- Pericapsular extension
- Structures that pass through the joint (eg, the cruciate lig-
aments) may act as a conduit for tumor growth (FIG 3)
- Transcapsular skip nodules: demonstrated in 1% of all
osteosarcomas
- Direct articular extension.

Metastatic Bone and Soft Tissue Sarcomas

- Unlike carcinomas, bone and soft tissue sarcomas dissemi-
nate almost exclusively through the blood. Hematogenous
spread of extremity sarcomas is manifested by pulmonary in-
volvement in the early stages and by bony involvement in later
stages. Abdominal and pelvic soft tissue sarcomas, on the
other hand, typically metastasize to the liver and lungs.
- Low-grade soft tissue sarcomas have a low (under 15%) rate
of subsequent metastasis, whereas high-grade lesions have a
significantly higher (over 20%) rate of metastasis.
- Metastases from sarcomas to regional lymph nodes are un-
common; the condition is observed in only 13% of patients
with soft tissue sarcomas and 7% of those with bone sarcomas

![FIG 2 • Extracompartmental extension. Ewing sarcoma of the distal two thirds of the femur (A) and osteosarcoma
of the proximal tibia (B). Note the extrasosseous component of the tumor. Most high-grade bone sarcomas are
bicompartamental at the time of presentation (ie, they involve the bone of origin as well as the adjacent soft
tissues). Tumors at that extent are staged as IIB. C. Plain radiograph of the proximal femur revealed direct
invasion through the cortical bone with a pathological fracture of the lesser trochanter (arrows). D. Axial MRI,
showing metastatic bladder carcinoma to the posterior thigh. E. In surgery, exploration of the sciatic nerve re-
vealed direct tumor involvement with extension under the epineural sheath. (Courtesy of Martin M. Malawer.)]
at initial presentation. The prognosis is similar to that of distant metastasis (FIG 4).

- Most patients with high-grade primary bone sarcomas, unlike soft tissue sarcomas, have distant micrometastases at presentation; an estimated 80% of patients with osteosarcomas have micrometastatic lung disease at the time of diagnosis. For this reason, in most cases, cure of a high-grade primary bone sarcoma can be achieved only with systemic chemotherapy and surgery.
- As mentioned, high-grade soft tissue sarcomas have a lower metastatic potential. Because of that difference in metastatic capability, the role of chemotherapy in the treatment of soft tissue sarcomas and its impact on survival are still matters of some controversy.

PROGNOSTIC FACTORS

- Prognostic factors for bone sarcomas include grade, size, extension of tumor beyond the bone cortex, regional and metastatic disease, and response of the tumor to chemotherapy (necrosis rate).
- Prognostic factors for soft tissue sarcomas include grade, tumor size, depth, age, margin status, location (proximal vs. distal), histologic subtypes, and metastatic disease.

Staging

- *Staging* is the process of classifying a tumor, especially a malignant tumor, with respect to its degree of differentiation, as well its local and distant extent, to plan the treatment and estimate the prognosis. Staging of a musculoskeletal tumor is based on the findings of the physical examination and the results of imaging studies. Biopsy and histopathological evaluation are essential components of staging but should always be the final step. An important variable in any staging system for musculoskeletal tumors, unlike a staging system for carcinomas, is the grade of the tumor.
- The system most commonly used for the staging of soft tissue sarcomas is the one developed by the American Joint Committee on Cancer (Table 1). It is based primarily on the Memorial–Sloan Kettering staging system and does not apply to rhabdomyosarcoma. Critics of this system point out that it is based largely on single-institution studies that were not subjected to multi-institutional tests of validity. The Musculoskeletal Tumor Society adopted staging systems that

mon. Therefore, there was a clear correlation between the extent of the tumor at presentation, its relation to the boundaries of the compartment in which it is located, and the extent of surgery. A close correlation also was found between surgical stage of bone sarcoma and patient survival (FIG 5). Since that time, the use of neoadjuvant chemotherapy has been shown to decrease tumor size and facilitate limb-sparing surgery, as well as reduce the local recurrence rate. As a result, compartmental resections have become rare. Nonetheless, Enneking’s classification is based on the biological behavior of soft tissue and bone sarcomas, and its underlying concept is as relevant today as it was in the early 1980s (Tables 1–4).

Approximate survival rates by stage for extremity soft tissue sarcomas are 90% for stage I, 70% for stage II, and 50% for stage III.

Staging Benign Bone Tumors

Enneking also described a staging system for benign bone tumors, which remains the one that is most commonly used (Table 4). That system is based on the biologic behavior of these tumors as suggested by their clinical manifestation and radiologic findings. Benign bone tumors grow in a centrifugal fashion, as do their malignant counterparts, and a rim of reactive bone typically is formed as a response of the host bone to the tumor. The extent of that reactive rim reflects the rate at which the tumor is growing: it usually is thick and well-defined around slowly growing tumors, and barely detectable around fast-growing, aggressive tumors.

- Latent benign bone tumors are classified as stage 1. Such tumors usually are asymptomatic and commonly are discovered as an incidental radiographic finding. Their natural history is of slow growth, and in most cases, they heal spontaneously. These lesions never become malignant and usually heal following simple curettage. Examples include fibrous cortical defects and nonossifying fibromas (FIG 6A).
- Active benign bone tumors are classified as stage 2 lesions. These tumors grow progressively but do not violate natural barriers. Associated symptoms may occur. Curettage and burr drilling are curative in most cases (FIG 6B–E).
- Aggressive benign bone tumors (stage 3) may cause destruction of surrounding bone and usually break through the cortex into the surrounding soft tissues. Local control can be achieved only by curettage and meticulous burr drilling with a local adjuvant such as liquid nitrogen, argon beam laser, or phenol. Wide resection of the lesion with a margin of normal tissue (FIG 6D,E) is another option.

EVALUATION OF THE PATIENT WITH A MUSCULOSKELETAL LESION

**Presenting Symptoms**

- Bone sarcomas typically present with pain that starts out as intermittent and progresses to a constant pain. Night pain often is a component. Pain typically is deep-seated and dull and may resemble that of a toothache. Patients with high-grade tumors present with a history of several months of pain. Patients with low-grade tumors, by contrast, present with a history of mild pain, typically lasting more than half a year. Local soft tissue swelling is common.
- Soft tissue sarcomas can arise anywhere in the body, but the lower extremities are the most common site. The incidence is as follows:
  - Lower extremities: 46%
  - Trunk: 19%
  - Upper extremities: 13%
  - Retroperitoneum: 12%
  - Head and neck: 9%
  - Other locations: 1%.
- The presenting symptoms and signs of soft tissue sarcomas are nonspecific. These lesions commonly present as a painless, slow-growing mass, but in 20% of patients they present as a painful, rapidly growing mass.

**Physical Examination**

- Patients with suspected musculoskeletal tumors should be examined thoroughly. The affected site is inspected for soft tis-
sue mass or swelling, overlying skin changes, lymphadenopathy, neurologic deficit, and vascular deficiency.

**Imaging and Other Staging Studies**

**Plain Radiography**
- Plain radiographs remain key in imaging bone tumors. Based on medical history, physical examination, and plain radiographs, bone tumors can be diagnosed accurately in over 80% of cases.
- Because of the fine trabecular detail revealed by plain radiographs, bone lesions of the extremities can be detected at an earlier stage; lesions of the spine and pelvis, however, are not diagnosed until a large volume of bone has been destroyed.
- Plain radiographs can show the location of the tumor in the bone, cortical destruction and thickening, periosteal response to the tumor (e.g., Codman’s triangle, sunburst), type of matrix produced by the tumor (osteoid, chondroid, fibrous), and soft tissue calcifications.

**Computed Tomography**
- Computed tomography (CT) is the imaging modality of choice to evaluate the extent of bone destruction. CT should be performed on a helical scanner that enables improved two-dimensional images and three-dimensional (3D) reconstruction capability. The field of view should be small enough to allow adequate resolution, particularly of the lesion and the adjacent neurovascular bundle and muscle groups. A slice thickness of 1 mm or less through the tumor enables accurate 3D reconstructions. Intravenous contrast dye should be employed to demonstrate the anatomic relation between the tumor and arterial vessels and to enhance soft tissue tumors, unless there is a clear contraindication for its use.
- Three-dimensional CT reconstruction with intravenous contrast accurately demonstrates blood vessels that are likely to be distorted or, less commonly, incorporated directly into the tumor mass. This information helps the surgeon plan the anatomic approach and gauge the likelihood that a major blood vessel has to be resected en bloc with the tumor (FIG 7A).
- Chest CT is the modality of choice when evaluating the patient for metastatic lung disease for both preoperative staging and postoperative follow-up (FIG 7B).

**Magnetic Resonance Imaging**
- Magnetic resonance imaging (MRI) has been proven to be superior to CT in the evaluation of the intramedullary and extrasosseous soft tissue extent of bone tumors (FIG 7C-F) and soft tissue sarcomas.
- Anatomic location and relation of the tumor can be defined accurately, because the signal intensity of a tumor is assessed by comparing it with that of the adjacent soft tissues, specifically skeletal muscle and subcutaneous fat. MRI also make it possible to view a lesion in all three planes (i.e., axial, sagittal, and coronal).
Contrast-enhanced MRI is useful in evaluating the relation between a tumor and the adjacent blood vessels and in characterizing cystic lesions. The anatomic relation between the tumor and peripheral nerves may be assessed. The presence of orthopaedic hardware or surgical clips is not a contraindication to the performance of MRI; however, if a lesion is immediately adjacent to the location of the hardware, the local field may be distorted.

MRI can accurately diagnose a variety of soft tissue tumors, including lipomas, liposarcomas, synovial cysts, pigmented villonodular synovitis, hemangiomas, and fibromatoses. Hematomas often have a characteristic appearance on MRI; however, high-grade sarcomas that have undergone significant intratumoral hemorrhage may resemble hematomas. For this reason, the diagnosis of a simple hemATOMa should be made cautiously, and, once it is made, close clinical monitoring must be made until the condition has been resolved. The general guidelines regarding narrowing of the field and recommended number of slices per tumor are similar to those for CT.

MRI allows accurate evaluation of the medullary extent of bone tumors to determine the level of bone resection with safe but narrow margins.

**Bone Scan**

Bone scan currently is used to determine the presence of metastatic and polyostotic bone disease and the involvement of a bone by an adjacent soft tissue sarcoma. This modality is more sensitive than plain radiographs for identifying bone lesions. The appearance of a bone lesion in the flow and pool phases of a three-phase bone scan reflects its biologic activity and may be helpful in differentiating between benign and malignant lesions. This feature is known as tumor blush. Malignant tumors show uptake in the late flow phase. Response to

---

**FIG 7**

A. Three-dimensional CT angiogram. This is a new technique for evaluating the relation between bony tumors and the adjacent arteries. This radiograph demonstrates the relationship of the popliteal artery and trifurcation to a posterior tibial osteosarcoma. Note the relation of the vessels to the tumor. B. CT scan showing lung metastases. C,D. Primary lymphoma of the distal femur. Plain radiographs suggest cortical integrity. This is confirmed by axial CT (E) and T2-weighted MRI (F), which demonstrates the intraosseous extent of the tumor. (continued)
FIG 7  •  (continued) **G.** MRI of a large thigh high-grade (Stage IIB) soft tissue sarcoma. The thigh is the most common site for extremity soft tissue sarcomas. MRI evaluation is the most useful study in determining the extent of soft tissue sarcomas. **H.** Bone scan of a proximal humeral (RT) osteosarcoma. **I.** Limb-sparing surgery for a proximal humeral osteosarcoma. The defect was reconstructed by a modular segmental prosthesis. **J.** Extensive giant cell tumor of the proximal tibia. Angiography performed prior to a proximal tibia resection documented an absent peroneal artery. A successful effort was made to preserve the anterior tibial artery during the resection; otherwise, the leg would have been dependent on a single vessel. **K.** Angiogram of a distal femoral (diaphyseal) osteosarcoma following induction chemotherapy. Note that the tumor is avascular. The decrease of tumor vascularity is an extremely reliable finding in predicting tumor necrosis. **L.** Gross specimen of a diaphyseal osteosarcoma following resection and induction chemotherapy. There was 100% tumor necrosis. **M.** Axillary venogram showing venous occlusion. Venography is especially useful in evaluating tumors of the pelvis and shoulder girdle. (C–F, J: Courtesy of Martin M. Malawer.)
chemotherapy can be evaluated by comparing the tumor blush before and after neoadjuvant chemotherapy.

**Angiography and Other Studies**

- Angiography is useful in demonstrating arterial displacement and occlusion, which are common in tumors that have a large extraosseous component. It also can detect vascular anomalies (FIG 7J) and establish patency of collateral vessels. Proximal femur resection, for example, often necessitates ligation of the profundus femoral artery (PFA). A patent superficial femoral artery (SFA) must be documented by angiography prior to surgery, otherwise, the extremity will suffer severe ischemia following ligation of the PFA. CT angiography is an emerging modality that will likely replace angiography in preoperative tumor evaluation.

- Preoperative embolization may be useful in preparing for resection of metastatic vascular carcinomas if an intrallesional procedure is anticipated. Metastatic hypernephroma is an extreme example of a vascular lesion that may bleed extensively and cause exsanguination without prior embolization.

- Serial angiographs may demonstrate reduced tumor vascularity as a result of chemotherapy treatment. Such a reduction has been shown to indicate a good response to preoperative chemotherapy (FIG 7K–L).

- **Venography**
  - Contrast venography demonstrates partial occlusion or complete obliteration of major veins as a result of direct tumor invasion or indirect compression by the tumor mass. Venography is used for direct assessment of deep vein thrombosis.
  - Venography also can indirectly assess tumor invasion into major nerves that lie in close proximity. Axillary tumors often are found to have invaded the brachial plexus when venography shows axillary vein occlusion (FIG 7M).

- **PET CT**
  - Positron emission tomography (PET) is a functional diagnostic imaging technique that provides very different information from that obtainable with other imaging modalities.

- The most widely used radiotracer is F-18 fluoro-2-deoxy-D-glucose (FDG), which is an analog of glucose. The FDG uptake in cells is directly proportional to glucose metabolism, which is increased many times in malignant cells. FDG-PET now is the standard of care in initial staging, monitoring the response to therapy and management of various cancers (eg, breast cancer, lung cancer, lymphoma).

- The introduction of combined PET-CT scanners, which provide not only functional but also structural information leading to a detection of subcentimeter lesions, has made this technique useful in the early detection of the disease process and in decreasing false-positive lesions. The FDG uptake is measured in SUV units, quantifying uptake and thereby differentiating malignant disease from other possible causes such as inflammatory or infectious processes.

**FIGURE 8** summarizes the use of the various imaging modalities in the staging process of a primary bone sarcoma.

**Biopsy**

- The concept and practice of biopsy of musculoskeletal tumors are discussed in Chapter ON-2.

**Laboratory Studies**

- Laboratory studies often are nonspecific. For patients younger than 40 years of age, they include a complete blood count with differential, peripheral blood smear, and erythrocyte sedimentation rate. Patients older than 40 years also need blood calcium and phosphate levels, serum and urine electrophoresis, and urinalysis.

- Serum alkaline phosphatase levels in primary osteosarcomas correlate with disease prognosis; therefore, pretreatment levels should be recorded.

**Formulating an Initial Assessment**

- Age of the patient
  - In younger patients (10–25 years), the common malignant bone tumors are osteosarcoma, Ewing sarcoma, and
leukemia. The common benign bone tumors are enchondroma, fibrous dysplasia, and eosinophilic granuloma.

- In the older age groups (40–80 years), the common malignant bone tumors are metastatic bone disease, myeloma, and lymphoma.
- Anatomic location of the tumor within the bone. Certain lesions have a predilection for occurring at particular locations:
  - Adamantinoma: in the tibia
  - Chondroblastoma: in the epiphysis of long bones
  - Giant cell tumor: in the metaphysis and extending through the epiphysis to lie just below the cartilage, typically around the knee
  - Osteosarcoma: in the metaphysis of the distal femur or proximal tibia
  - Parosteal osteosarcoma: in the distal femur (posterior cortex)
  - Chondrosarcoma: in the pelvis
  - Chordoma: in the sacrum
  - Synovial sarcoma: in the foot and ankle
  - Enchondroma and metastatic lung carcinoma: in the fingers
- The effect of the lesion on the bone
  - High-grade lesions spread rapidly, causing early cortical bone destruction and expansion. The typical lytic appearance is permeative or moth-eaten.
  - Low-grade tumors spread at a slower pace, but may still destroy cortical bone and produce a soft tissue mass.
- The response of the bone to the lesion.
  - High-grade lesions spread rapidly and give the bone little ability to contain the process. Cortical destruction, periosteal elevation (eg, Codman’s triangle, onion skin appearance), and soft tissue spread (sunburst appearance) often are seen.
- Matrix production
  - Osteoid mineralization often is cloudlike and is typical of bone-forming tumors.
  - Cartilage calcification often appears stippled and is characteristic of cartilage-forming tumors.
  - Fibrous-forming tumors have a typical “ground glass” appearance

**SURGICAL MANAGEMENT**

**Classification of Surgical Procedures**

- Four basic types of excisions are used, each of which is based on the relation between the dissection plane and the tumor and its pseudocapsule: intralesional, marginal, wide, and radical excisions (FIG 9).
  - An **intralesional excision** is performed within the tumor mass and results in removal of only a portion of the tumor; the pseudocapsule and macroscopic tumor are left behind.
  - In a **marginal excision**, the dissection plane passes through the pseudocapsule of the tumor. Such a resection may leave microscopic disease.
  - **Wide (en bloc) excision** entails removal of the tumor, its pseudocapsule, and a cuff of normal tissue surrounding the tumor in all directions. This is the desired resection margin for sarcoma; however, the adequate thickness of the normal tissue cuff is a matter of some controversy. For both soft tissue and bone sarcomas, it generally is believed to be between 0.5 and 2 cm.
  - **Radical excision** involves removal of the tumor and the entire anatomic compartment within which it arises. Although traditionally mentioned as the fourth excision type, it does not define the component of the tumor that is left behind. In other words, a radical excision can achieve a marginal or a wide margin, depending on how close the tumor is to the border of the compartment. However, radical excision excludes the possibility of skip metastases.
- In general, benign bone tumors are adequately treated by either an intralesional procedure (eg, curettage and burr drilling, cryosurgery) or by marginal excision. Primary bone sarcomas are treated with wide excision. Metastatic tumors are treated according to the general intent of the surgery. When a palliative surgery is performed, metastatic lesions are treated by an intralesional procedure. If a curative procedure is performed, as in the case of solitary breast metastasis, for example, the lesion is treated as if it was a primary bone sarcoma (ie, wide excision).
Successful limb-sparing surgery consists of three phases:
- Resection of tumor. Resection follows the principles of oncologic surgery strictly. Avoiding local recurrence is the criterion of success and the main determinant of the amount of bone and soft tissue to be removed.
- Skeletal reconstruction. The average skeletal defect following adequate bone tumor resection measures 15 to 20 cm. Techniques of reconstruction (eg, prosthetic replacement [FIG 10], arthrodesis, allograft, or combination) vary and are independent of the resection, although the degree of resection may favor one technique over the other.
- Soft tissue and muscle transfers. Muscle transfers are performed to cover and close the resection site and to restore lost motor power. Adequate skin and muscle coverage is mandatory to decrease postoperative morbidity.

Guidelines for Surgical Resection
- The major neurovascular bundle must be free of tumor.
- Wide resection of the affected bone with a normal muscle cuff in all directions should be achieved.
- All previous biopsy sites and all potentially contaminated tissues should be removed en bloc.
- Bone should be resected 3 to 4 cm beyond abnormal uptake as determined by bone scan. (This is a safe margin to avoid intraosseous tumor extension.)
- The adjacent joint and joint capsule should be resected.
- Adequate motor reconstruction must be accomplished by regional muscle transfers.
- Adequate soft tissue coverage is needed to decrease the risk of skin flap necrosis and secondary infection. 5

MALIGNANT BONE TUMORS
- Primary malignancies of bone arise from mesenchymal cells (sarcoma) and bone marrow cells (myeloma and lymphoma). Bone also is a common site of metastasis from a variety of carcinomas. Osteosarcoma and Ewing sarcoma, the most common malignant mesenchymal bone tumors, usually occur during childhood and adolescence. Other mesenchymal tumors (eg, MFH, fibrosarcoma, chondrosarcoma), while occasionally seen in childhood, are more common in adults. Multiple myeloma and metastatic carcinoma typically increase in frequency with increasing patient age and usually are seen in patients over 40 years of age. This section describes the clinical, radiographic, and pathological characteristics and treatment of the primary bone sarcomas.
- Osteosarcoma provides the model on which treatment of all other sarcomas is based. The effectiveness of multiagent chemotherapy regimens has been proven with the increase in overall survival rates from the bleak statistic of 15% to 20% with surgery alone in the 1970s to 55% to 80% today. In par-
Osteosarcoma

- Osteosarcoma is the most common primary bone sarcoma. Osteosarcoma (OS) is a high-grade malignant spindle cell tumor arising within a bone. Its distinguishing characteristic is the production of “tumor” osteoid, or immature bone, directly from a malignant spindle cell stroma. OS typically occurs during childhood and adolescence. In patients over the age of 40, it usually is associated with a preexistent disease such as Paget disease, irradiated bones, multiple hereditary exostosis, or polyostotic fibrous dysplasia.

- The incidence of osteosarcoma peaks to 8 per million per year between the ages of 10 and 20 years. Survival of osteosarcoma patients has improved greatly over the past 30 years. The 5-year survival rate is 60%, except in patients over age 45, where it is 40%.

- The most common bone sites are the knee joint (50%) and the proximal humerus (25%). Between 80% and 90% of osteosarcomas occur in the long tubular bones; the axial skeleton rarely is affected (FIG 11).

- Pain, accompanied by a tender soft tissue swelling, is the most common complaint on presentation, with a firm, soft tissue mass fixed to the underlying bone found on physical examination. Systemic symptoms are rare. The incidence of pathologic fractures is less than 1%.

Radiographic Characteristics

- Typical radiographic findings include increased intramedullary sclerosis due to tumor bone or calcified cartilage; an area of radiolucency due to nonossified tumor; a pattern of permeative destruction with poorly defined borders; cortical destruction; periosteal elevation; and extrasosseous extension with soft tissue ossification. This combination of characteristics is not seen with any other lesion.

- Three broad categories are based on radiographic evaluation (FIG 12A–C): sclerotic osteosarcoma (32%), osteolytic osteosarcoma (22%), and mixed (46%). Although there is no statistically significant difference among overall survival rates of these types, it is important to recognize the patterns. The sclerotic and mixed types offer few diagnostic problems. Errors of diagnosis most often occur with pure osteolytic tumors. The differential diagnosis of osteolytic osteosarcoma includes giant cell tumor, aneurysmal bone cyst, fibrosarcoma, and MFH.

Microscopic Characteristics

- The diagnosis of osteosarcoma is based on the following findings:
  - Identification of a malignant stroma that produces unequivocal osteoid matrix. The stroma consists of a haphazard arrangement of highly atypical cells.
  - Pleomorphic cells that contain hyperchromatic, irregular nuclei. Mitotic figures, often atypical, usually are easy to identify. Between these cells is a delicate, lacelike eosinophilic matrix, assumed to be malignant osteoid (FIG 12D).
  - The predominance of one tissue type in many osteosarcomas has led to a histologic subclassification of this neoplasm.
    - The term osteoblastic osteosarcoma is used for those tumors in which the production of malignant osteoid prevails. Calcification of the matrix is variable.
    - Some tumors reveal a predominance of malignant cartilage production; hence, they are referred to as chondroblastic osteosarcoma. Even though the malignant cartilaginous elements may be overwhelming, the presence of a malignant osteoid matrix warrants the diagnosis of osteosarcoma.
    - Yet another variant is characterized by large areas of proliferating fibroblasts, arranged in intersecting fascicles. Such areas are indistinguishable from fibrosarcoma, and thorough sampling may be necessary to identify the malignant osteoid component.
  - As the neoplasm permeates the cortex, the periosteum may be elevated. This stimulates reactive bone formation and accounts for a distinctive radiologic feature called “Codman’s triangle.” Longitudinal sectioning of the involved bone often reveals wide extension within the marrow cavity. Rarely, skip areas within the medullary canal can be demonstrated. There may be necrotic and hemorrhagic foci. At the time of diagnosis, most tumors already have caused substantial cortical destruction. Continued tumor growth results in involvement of the adjacent soft tissues (FIG 12E).

Natural History and Chemotherapy

- Prior to the development of adjuvant chemotherapy, effective treatment was limited to radical margin amputation. Metastasis to the lungs and other bones generally occurred within 24 months. Overall survival rates 2 years after surgery ranged from 5% to 20%. No significant correlation between overall survival and histologic subtypes, tumor size, patient age, or degree of malignancy was seen. The most significant clinical variable
The three radiographic matrix types of osteosarcoma: osteolytic (A; arrows indicate tumor); mixed (B); and sclerosing (C). There is no prognostic difference in survival based on the radiographic type of matrix formation.

D. Classical high-grade osteosarcoma reveals a population of pleomorphic spindle cells intimately associated with a mesh of immature lacy osteoid. The amount of osteoid can be minimal, or it may be a predominant element forming wide intersecting trabeculae lined by the malignant osteoblasts. Giant cells also can be present.

E. Pathologic specimen. High-grade osteosarcoma of the proximal humerus with cortical breakthrough and tumor extension into the soft tissues.

F. CT scan demonstrating a large pelvic osteosarcoma. (A-E: Courtesy of Martin M. Malawer.)
was anatomic site: pelvic and axial lesions had a lower survival rate compared with extremity tumors, and tibial lesions had a better survival rate than femoral lesions (FIG 12F).

- The dismal outcome associated with osteosarcoma has been altered dramatically by adjuvant chemotherapy and also by aggressive thoracotomy for pulmonary disease. No difference in local recurrence or overall survival was seen between patients undergoing amputation and those undergoing limb-sparing surgery.

**Overall Treatment Strategy**

- The patient with a primary tumor of the extremity without evidence of metastases requires surgery to control the primary tumor and chemotherapy to control micrometastatic disease. From 80% to 90% of all patients with osteosarcoma fall into this category.

- Chemotherapy protocols typically have included various combinations and dosage schedules of high-dose methotrexate (HDMTX), doxorubicin hydrochloride (Adriamycin), and cisplatin. Ifosfamide, which is as effective as Adriamycin in single-agent studies, recently has supplanted methotrexate in many ongoing protocols. Multiagent chemotherapy, using various dosing schedules, now is considered standard treatment for osteosarcoma. Success with adjuvant chemotherapy led to investigation of treatment in the neoadjuvant (preoperative) setting. When used in that setting, tumor response results in shrinkage of the soft tissue components, facilitating surgical excision and subsequent limb salvage. Tumor response is measured by tumor necrosis rate on microscopic pathology and is a significant prognostic factor.

- Limb-salvage surgery is a safe surgical procedure for approximately 85% to 90% of patients. This technique may be used for all spindle cell sarcomas, regardless of histogenesis. The majority of OSs can be treated safely by a limb-sparing resection combined with effective adjuvant treatments. The successful management of localized OS and other sarcomas requires careful coordination and timing of staging studies, biopsy, surgery, and preoperative and postoperative chemotherapy, radiation therapy, or both. The site of the lesion is evaluated as previously described. Preoperative studies allow the surgeon to understand the local anatomy and the volume of tissue to be resected and reconstructed.

- Surgery alone results in a cure rate of 15% to 20% at best. The choice between amputation and limb-sparing resection must be made by an experienced orthopaedic oncologist, taking into account tumor location, size, or extramedullary extent; the presence or absence of distant metastatic disease; and patient factors such as age, skeletal development, and lifestyle preference that might dictate the suitability of limb salvage or amputation. Routine amputations are no longer performed; all patients should be evaluated for limb-sparing options. Intensive, multiagent chemotherapeutic regimens have provided the best results to date. Patients who are judged unsuitable for limb-sparing options may be candidates for presurgical chemotherapy; those with a good response may then become suitable candidates for limb-sparing operations. The management of these patients mandates close cooperation between chemotherapist and surgeon.

**Variants of Osteosarcoma**

- There are 11 recognizable variants of the classic OS. OS arising in the jaw bones is the most common of these. Parosteal and periosteal OS are the most common variants of the classic OS occurring in the extremities. In contrast to classic OS, which arises within a bone (intramedullary), parosteal and periosteal OS arises on the surface (juxtacortical) of the bone. Parosteal osteosarcoma is the most common of the unusual variants, representing about 4% of all osteosarcomas.

**Parosteal Osteosarcoma**

- Parosteal osteosarcoma is a distinct variant of osteosarcoma. Its prevalence is estimated to be 4%. It arises from the cortical bone and generally occurs in an older age group and has a better overall prognosis than osteosarcoma. As in osteosarcoma, the distal femur is the most common location; characteristically, the tumor attaches to its posterior aspect (FIG 13A–C). The proximal humerus and the proximal tibia are the next most common sites. Parosteal osteosarcomas usually present as a mass, occasionally associated with pain. The natural history is slow growth and late metastasis. The long-term survival rate is 75% to 85%. The tumor arises from the cortical surface and presents as a protuberant multinodular mass. The surface of the lesion may be covered in part by a cartilaginous cap resembling an osteochondroma; other areas may infiltrate into the adjacent soft tissues. The tumor usually encircles, partially or completely, the shaft of the underlying bone. In contrast to osteochondromas, the medullary canal of the bone is not contiguous with that of the neoplasm. Radiologically, parosteal osteosarcoma presents as a large, dense, tabulated mass that is broadly attached to the underlying bone without involvement of the medullary canal (FIG 13D,E). If present long enough, the tumor may encircle the entire bone. The periphery of the lesion typically is less mature than the base. Despite careful evaluation, intramedullary extension is difficult to determine from plain radiographs. It is more accurately detected with CT scan.

- Diagnosis of parosteal osteosarcoma, more than that of other bone tumors, must be based on the clinical, radiologic, and pathologic findings (FIG 13F–H). Most parosteal osteosarcomas are low grade; they do not require neoadjuvant and adjuvant chemotherapy, and are best treated with wide excision. This tumor commonly is mislabeled by inexperienced clinicians and pathologists as osteochondroma, myositis ossificans, or conventional osteosarcoma. In the classic low-grade lesion, irregularly formed osteoid trabeculae, usually of woven bone, are surrounded by a spindle cell stroma containing widely spaced, bland-appearing fibroblastic spindle cells (FIG 13I). There may be foci of atypical chondroid differentiation. With the higher grades the likelihood of intramedullary involvement is increased. This, in turn, correlates well with the presence of distant metastases.

**Chondrosarcomas (Central and Peripheral)**

**Clinical Characteristics and Physical Examination**

- Half of all chondrosarcomas occur in persons over the age of 40. The most common sites are the pelvis, femur, and shoulder girdle. The clinical presentation varies. Peripheral chondrosarcomas may become quite large without causing pain, and local symptoms develop only because of mechanical irritation. Pelvic chondrosarcomas often are large and present with referred pain to the back or thigh, sciatica secondary to sacral plexus irritation, urinary symptoms from bladder neck involvement, unilateral edema due to iliac vein obstruction, or as a painless abdominal mass. Conversely, central chondrosar-
FIG 13  A. Gross specimen of a resection of a distal femoral osteosarcoma. The average bony defect is 15 to 20 cm. Note how the biopsy site is removed en bloc with the tumor. The proximal tibia routinely is removed en bloc. The length of bone resected is determined by preoperative CT and MRI evaluation. B. CT scan of a typical parosteal osteosarcoma. C. Gross specimen of a distal femoral parosteal osteosarcoma. There is minimal intraosseous extension. D,E. Plain radiographs of the distal femur, AP (D) and lateral (E) views, show a dense, irregular, sclerotic lesion, attached to the posterior femoral cortex. The posterior aspect of the distal femur is a classic location for parosteal osteosarcomas, and that diagnosis should be considered for any sclerotic lesion in that location. F. The relation of the parosteal osteosarcoma to the medullary canal is better viewed on this CT scan, which shows no tumor extension to the canal. In contrast to osteochondromas, the medullary canal of the bone is not contiguous with that of the tumor. G. Gross pathological specimen. H. Specimen shown illuminated with tetracycline fluorescence, which demonstrates minimal medullary tumor extension through the posterior cortex. I. Parosteal osteosarcoma. There are parallel or intersecting osseous trabeculae (arrows) that may be either lamellar or woven-type bone matrix. The intervening fibrocollagenous tissue is composed of bland, widely-spaced fibroblastic cells. (D–I: Courtesy of Martin M. Malawer.)
Comas present with dull pain. A mass is rarely present. Pain, which indicates active growth, is an ominous sign of a central cartilage lesion. This cannot be overemphasized. An adult with a plain radiograph suggestive of a “benign” cartilage tumor but who is experiencing pain most likely has a chondrosarcoma (FIG 14A).

**Radiographic Findings**
- Central chondrosarcomas have two distinct radiological patterns. One is a small, well-defined lytic lesion with a narrow zone of transition and surrounding sclerosis with faint calcification. This is the most common malignant bone tumor that may appear radiographically benign (FIG 14B,C).
- The second type has no sclerotic border and is difficult to localize. The key sign of malignancy is endosteal scalloping. This type is difficult to diagnose on plain radiographs and may go undetected for a long period of time.
- Peripheral chondrosarcoma is easily recognized as a large mass of characteristic calcification protruding from a bone. Correlation of the clinical, radiographic, and histologic data is essential for accurate diagnosis and evaluation of the aggressiveness of cartilage tumor. In general, proximal or axial location, skeletal maturity, and pain point toward malignancy, even though the cartilage may appear benign.

**Grading and Prognosis**
- Chondrosarcomas are graded 1, 2, and 3; most are either grade 1 or grade 2. The metastatic rate of moderate-grade versus high-grade is 15% to 40% versus 75%. Grade 3 lesions have the same metastatic potential as osteosarcomas.
- In general, peripheral chondrosarcomas are a lower grade than central lesions. Ten-year survival rates among those with peripheral lesions are 77% with 32% among those with central lesions.

Secondary chondrosarcomas arising from osteochondromas (FIG 14D,E) also have a low malignant potential; 85% are grade 1. The multiple forms of benign osteochondromas or en-chondromas have a higher rate of malignant transformation than the corresponding solitary lesions. The pelvis, shoulder girdle, and ribs are the most common sites of malignant transformation of osteochondromas. The risk of malignant transformation is approximately 20% to 25%.

**Microscopic Characteristics**
- The histologic spectrum of chondrosarcomas varies tremendously. High-grade examples are easy to identify, whereas certain low-grade tumors are exceedingly difficult to distinguish from chondromas. Correlation between the histologic features (FIG 14F) and both the clinical setting and the radiographic changes is, therefore, of utmost importance in avoiding serious diagnostic error. The grade of malignant cartilaginous tumors correlates with clinical behavior. Grade I tumors are characterized by an increased number of chondrocytes set in a matrix that is chondroid to focally myxoid.
- Areas of increased cellularity with more marked variation in cell size, significant nuclear atypia, and frequent pleomorphic forms define a grade 2 lesion. Binuclear forms are more common in this group.
- Grade 3 chondrosarcomas, which are relatively uncommon, show even greater cellularity, often with spindle cell areas, and reveal prominent mitotic activity. Chondrocytes may contain large, bizarre nuclei. Areas of myxoid change are common.

**Treatment**
- The treatment of chondrosarcoma is surgical removal. Guidelines for resection for high-grade chondrosarcomas are similar to those for OSs. The sites of origin and the fact that chondrosarcomas tend to be low-grade often make them amenable to limb-sparing procedures. The four most common sites are the pelvis, proximal femur, shoulder girdle, and diaphyseal portions of the long bones.

**Variants of Chondrosarcoma**
- There are three less-common variants of classic chondrosarcoma. Each is briefly described below (FIG 15).
- Clear cell chondrosarcoma, the rarest form of chondrosarcoma, is a slow-growing, locally recurrent tumor resembling a chondroblastoma but with some malignant potential that typically occurs in adults. The most difficult clinical problem is early recognition; it often is confused with chondroblastoma. Metastases occur only after multiple local recurrences. Primary treatment is wide excision. Systemic therapy is not required.
- Mesenchymal chondrosarcoma is a rare, aggressive variant of chondrosarcoma characterized by a biphasic histologic pattern, ie, small, compact cells intermixed with islands of cartilaginous matrix. This tumor has a predilection for flat bones; long tubular bones rarely are affected. It tends to occur in the younger age group and has a high metastatic potential. The 10-year survival rate is 28%. This type responds favorably to radiation therapy.
- Dedifferentiated chondrosarcoma. About 10% of chondrosarcomas may dedifferentiate into either a fibrosarcoma or an OS. They occur in older individuals and often are fatal. Surgical treatment is similar to that described for other high-grade sarcomas. Adjuvant therapy is warranted.

**Ewing Sarcoma**
- Ewing sarcoma is the second most common bone sarcoma of childhood; it is approximately one half as common as osteosarcoma. The lesion is characterized by poorly differentiated, small, round cells with marked homogeneity. The exact cell of origin is unknown. These mesenchymal cells are rich in glycogen and typically manifest a unique reciprocal chromosomal translocation, t(11;22)(q24;q12) that results in a chimeric protein, EWS/FLI-1. This translocation occurs in approximately 90% of these tumors. The clinical and biologic behavior is significantly different from that of spindle cell sarcomas. Within the past 2 decades, the prognosis of patients with Ewing sarcomas has been improved dramatically thanks to a combination of adjuvant chemotherapy, improved radiation therapy techniques, and the select use of limited surgical resection.

**Clinical Characteristics and Physical Examination**
- Ewing sarcomas tend to occur in young children, although rarely in those younger than 5 years. The flat and axial bones are involved in 50% to 60% of cases. When a long (tubular) bone is involved, it most often is the proximal or diaphyseal area that is affected (FIG 16). In contrast, OSs occur in adolescence (average age 15), most often around the knees, and involve the metaphysis of long bones.

Another unique finding with Ewing sarcomas is systemic signs, ie, fever, anorexia, weight loss, leukocytosis, and anemia. All may be a presenting sign of the disease and are seen in 20% to 30% of patients; this is in contrast to the distinct
absence of systemic signs with OS until late in the disease process. The most common complaint is pain or a mass. Localized tenderness often is present with associated erythema and induration. These findings, in combination with systemic signs of fever and leukocytosis, closely mimic those of osteomyelitis.

Radiographic Findings

- Ewing sarcoma is a highly destructive radiolucent lesion without evidence of bone formation. The typical pattern consists of a permeative or moth-eaten destruction associated with periosteal elevation. Multilaminated periosteal elevation (onion skin appearance) or a sunburst appearance is
FIG 15 • A,B. Plain radiographs of the proximal tibia: AP and lateral views show a central chondrosarcoma (arrows). Macrosections of central chondrosarcomas of the proximal tibia (C) and proximal femur (D). E. Plain radiograph of the femoral shaft shows a central chondrosarcoma, presenting as a well-defined lytic lesion with a sharp transition zone, calcifications, and endosteal scalloping. Immunohistochemical stains, differentiation among these tumors has become simpler. F. Cross-section of an intramedullary chondrosarcoma discloses its lobular architecture and translucent, hyaline-like matrix. Note the characteristic endosteal erosions (arrows). G. Low-grade chondrosarcoma maintains a lobular architecture. There is slightly increased cellularity, occasional binucleate cells, and nuclear atypia. These cells typically are found in lacunae. The tumor tends to permeate between the normal osseous trabeculae. H. The juxtaposition of high-grade spindle sarcoma with lobules of low-grade chondrosarcoma is the hallmark of dedifferentiated chondrosarcoma. The spindle cell component usually reveals features of malignant fibrous histiocytoma, osteosarcoma, or it may be unclassifiable. This neoplasm pursues an aggressive clinical course with very low long-term survival. (Courtesy of Martin M. Malawer.)
characteristic. When Ewing sarcoma occurs in flat bones, however, these findings usually are absent. Tumors of flat bones appear as a destructive lesion with a large soft tissue component. The ribs and pelvis are involved most often. Pathologic fractures occur secondary to extensive bony destruction and the absence of tumor matrix.

The differential diagnosis is osteomyelitis, osteolytic osteosarcoma, metastatic neuroblastoma, and eosinophilic granuloma.

**Natural History**
- Ewing sarcoma is highly lethal and disseminates rapidly. Historically, fewer than 10% to 15% of patients remained disease free at 2 years.

Many patients present with metastatic disease. The most common sites for metastases are other bones and the lungs. Ewing sarcoma once was thought to be a multicentric disease because of the high incidence of multiple bone involvement. Unlike other bone sarcomas, Ewing sarcoma is associated with visceral, lymphatic, and meningeal involvement, and all of these areas must be investigated.

**Radiographic Evaluation and Staging**
- No general staging system for Ewing sarcoma exists. The musculoskeletal staging system does not apply to the round cell sarcomas of the bone.

Because these lesions have a propensity to spread to other bones, bone marrow, the lymphatic system, and the viscera, evaluation is more extensive than that for spindle cell sarcomas. It must include a careful clinical examination of regional and distal lymph nodes and radiographic evaluation for visceral involvement. Liver–spleen scans and bone marrow aspirates are required, in addition to CT of the lungs and the primary site. Angiography is required only if a primary resection is planned.

**Microscopic Characteristics**
- Because accurate pathological interpretation often is difficult, and bone heating is subject to several potential problems, the following guidelines have been established for the biopsy of suspected round cell tumors:
  - Adequate material must be obtained for histologic evaluation and electron microscopy.
  - Routine cultures should be made to aid in the differentiation from osteomyelitis.
  - Biopsy of the bony component is not necessary. The soft tissue component usually provides adequate material. Bone biopsy should be through a small hole on the compressive side of the bone. Pathologic fracture through an irradiated bone often does not heal.
  - Large nests and sheets of relatively uniform round cells are typical. The sheets often are compartmentalized by intersecting collagenous trabeculae. The cells contain round nuclei with a distinct nuclear envelope. Nucleoli are uncommon, and mitotic activity is minimal. Occasional rosette-like structures may be found, although neuroectodermal origin has never been confirmed. In the vicinity of necrotic tumor, small pyknotic cells may be observed. Vessels in these necrotic regions often are encircled by viable tumor cells. The cells often contain cytoplasmic glycogen. Thicn neoplasm belongs to the category of small blue round cell tumors, a designation that also includes neuroblastoma, lymphoma, metastatic OS, and, occasionally, osteomyelitis and histiocytosis. When confronted with this differential diagnosis, the pathologist may turn to electron microscopy or immunohistochemistry for additional information.

**Combined Multimodality Treatment**
- Ewing sarcomas generally are considered radiosensitive. Radiation therapy to the primary site has been the traditional mode of local control. Within the past decade, surgical resec-
tumors has become increasingly popular. Although detailed management is beyond the scope of this chapter, the following sections summarize some common aspects of the multimodality approach.

**Chemotherapy**
- Doxorubicin, actinomycin D, cyclophosphamide, and vincristine are the most effective agents. A variety of different combinations and schedules are used. All patients require intensive chemotherapy to prevent dissemination. Overall survival in patients with lesions of the extremities now ranges between 40% and 75%.

**Radiation Therapy**
- Radiation must be administered to the entire bone at risk. The usual dose is 4500 to 6000 cGy, delivered over 6 to 8 weeks. To reduce the morbidity of radiation, it is recommended that between 4000 and 5000 cGy be delivered to the whole bone, with an additional 1000 to 1500 cGy given to the tumor site.

**Surgical Treatment**
- The role of surgery in the treatment of Ewing sarcoma currently is changing. The Intergroup Ewing’s Study recommends surgical removal of “expendable” bones such as the ribs, clavicle, and scapula. In general, surgery is reserved for tumors located in high-risk areas, eg, the ribs, ilium, and proximal femur. Risk is defined as an increased incidence of local recurrence and metastases. In general, surgery is considered an adjunct to the other treatment modalities.
- Interest recently has increased in primary resection of Ewing sarcoma following induction (neoadjuvant) chemotherapy, similar to the treatment of osteosarcoma. When this resection is performed, radiation therapy is not given if the surgical margins are negative (ie, wide resection). The goal of this approach is to increase local control as well as minimize the complications and functional losses that are associated with high-dose radiation therapy given to a young patient.

**Giant Cell Tumor of Bone**
- Giant cell tumor of bone (GCT) is a benign aggressive, locally recurrent tumor with a low metastatic potential (4%–8%). Giant cell sarcoma of bone refers to a de novo, malignant GCT, not to the tumor that arises from the transformation of a GCT previously thought to be benign. These two lesions are separate clinical entities.

**Clinical Characteristics and Physical Examination**
- GCTs occur slightly more often in females than in males. Eighty percent of GCTs in the long bones occur after skeletal maturity; 75% of these develop around the knee joint. A joint effusion or pathologic fracture, uncommon with other sarcomas, is common with GCTs. GCTs occasionally occur in the distal radius, the vertebrae (2%–5%), and the sacrum (10%).

**Natural History and Potential Malignancy**
- Although GCTs rarely are malignant de novo (2%–8%), they may undergo transformation and demonstrate malignant potential histologically and clinically after multiple local recurrences. Between 8% and 22% of known GCTs become malignant following local recurrence. This rate decreases to less than 10% if patients who have undergone radiation therapy are excluded. Approximately 40% of malignant GCTs become malignant at the first recurrence. The remainder typically become malignant by the second or third recurrence; thus, each recurrence increases the risk of malignant transformation. A recurrence after 5 years is extremely suspicious for a malignancy. Primary malignant GCT generally has a better prognosis than does secondary malignant transformation of typical GCT, especially if the transformation occurs after radiation therapy. Local recurrence of a GCT is determined by the adequacy of surgical removal rather than by histologic grade.

**Radiographic and Clinical Evaluation**
- GCTs are eccentric lytic lesions without matrix production occurring at the end of long bones. About 10% are axial. They have poorly defined borders with a wide area of transition. They are juxtaepiphysial with a metaphysial component. Although the cortex is expanded and appears destroyed, at surgery it usually is found to be attenuated but intact. Periosteal elevation is rare; soft tissue extension is common. In the skeletally immature patient, GCT must be differentiated from aneurysmal bone cyst, although both lesions are closely related. GCTs are classified as type I, II, or III using the Enneking staging system.

**Microscopic Characteristics**
- Two basic cell types constitute the typical GCT.
  - The stroma is characterized by polygonal to somewhat spindled cells containing central round nuclei.
  - Benign, multinucleated giant cells are scattered diffusely throughout the stroma. Small foci of osteoid matrix, produced by the benign stroma cells, can be observed; however, chondroid matrix never occurs.

**Treatment**
- Treatment of GCT of bone is surgical removal. In general, curettage of the bony cavity with “cleaning” of the walls with a high-speed burr drill and the use of a physical adjuvant will kill any cells remaining within the cavity wall. We prefer the combined use of cryosurgery (either liquid nitrogen or a closed system of argon and helium) to obtain temperatures of −40°C. The cavity is then reconstructed with bone graft, polymethylmethacrylate, and internal fixation devices, which permit early mobilization.
- Cryosurgery has been used with more success for GCTs than for any other type of bone tumor. Cryosurgery is effective in eradicating the tumor while preserving joint motion and avoiding the need for resection or amputation. Liquid nitrogen is a very effective physical adjuvant and is recommended following curettage resection. Curettage alone is not recommended because of the associated high rate of local recurrence.

**COMMON SOFT TISSUE SARCOMAS**

**Treatment**
- The treatment of high-grade soft tissue sarcomas (STS) has undergone fundamental changes within the past decade. Treatment of these patients requires a multimodality approach, and successful management requires cooperation among the surgeon, medical oncologist, and radiation oncologist. The appropriate role of each modality is continuously changing, but general descriptions are provided in the following sections.

**Chemotherapy**
- The impact of chemotherapy for high-grade STS on survival remains controversial. Combination chemotherapy has been shown to be more effective than single-agent therapy in
preventing pulmonary dissemination from high-grade sarcomas. The most effective drugs in use today are doxorubicin hydrochloride (Adriamycin) and ifosfamide. Dacarbazine, methotrexate, and cisplatin also have activity against these tumors and are included in many current protocols. The various combinations traditionally are given in an adjuvant (postoperative) setting and are presumed effective against clinically undetectable micrometastases. Neoadjuvant (preoperative) chemotherapy is being evaluated in several institutions. Early results have indicated that significant reduction in tumor size can occur, thereby facilitating attempts at limb salvage. In patients with tumors deemed unresectable who are therefore destined for limb amputation, the tumors may shrink drastically in response to preoperative chemotherapy, thereby making them candidates for wide resection and limb-sparing surgery.

Radiation Therapy
- Radiation typically is administered in a dose of 5000 to 6500 cGy over many fractions. This modality is effective in an adjuvant setting in decreasing local recurrence following nonablative resection. The degree to which the initial surgical volume should be decreased in these circumstances is controversial, although the rate of local recurrence following a wide excision and postoperative radiation therapy is 5% to 10%. Radiation therapy includes irradiating all the tissues at risk, shrinking fields, preserving a strip of unirradiated skin, and using filters and radiosensitizers. Local morbidity has been greatly decreased within the past decade. Preoperative radiation is effective in reducing tumor volume but is associated with increased morbidity resulting from significant wound-healing complications and, therefore, is not recommended as often as postoperative radiation.

Surgery
- Removal of the tumor is necessary to achieve local control, by either a nonablative resection (limb salvage) or an amputation. The procedure chosen depends on results of the preoperative staging studies. A prospective randomized National Cancer Institute (NCI) trial established that a multimodality approach employing limb-salvage surgery combined with adjuvant radiation and chemotherapy offered local control and survival rates comparable to those of amputation plus chemotherapy, while simultaneously preserving a functional extremity.
- The use of adjuvant therapy (chemotherapy or radiation) permits limb-sparing procedures for most extremity soft tissue sarcomas. Enneking et al\(^3,4\) have shown that a radical resection for an STS has a local recurrence rate of about 5% with surgery alone. Wide excision (without adjuvant radiation or chemotherapy) has a 50% rate of local failure. Results from the NCI showed that the rate of local recurrence decreased to 5% following local excision (either a marginal or wide excision) when combined with postoperative radiation therapy and chemotherapy. Others have reported similar good results from preoperative radiation, with or without preoperative chemotherapy. Contraindications to limb-sparing surgery are similar to those for the bony sarcomas. In general, nerve or major vascular involvement is a contraindication.
- Studies of referred patients show that approximately half of all patients with soft tissue sarcomas treated with attempted excisional biopsy by the referring surgeon will have microscopic or gross tumor remaining. As a result, referred patients undergo routine re-resection of the surgical site to ensure adequate local control prior to institution of adjuvant treatment.

**GENERAL SURGICAL TECHNIQUE AND CONSIDERATIONS**
- All tissue at risk should be removed with a wide, en bloc excision that includes the tumor, a cuff of normal muscle, and all potentially contaminated tissues. It is not necessary to remove the entire muscle group. The biopsy site should be removed with 3 cm of normal skin and subcutaneous tissue en bloc with the tumor.
- The tumor or pseudocapsule should never be visualized during the procedure (FIG 17). Contamination of the wound with tumor greatly increases the risk of local recurrence.
- Distant flaps should not be developed at the time of resection. This may contaminate a noninvolved area.
- The margin surrounding the surgical wound should be marked with metallic staples to help the radiotherapist determine the high-risk area if radiation treatment is needed later.
- Reconstruction of the defect should include local muscle transfers to protect exposed neurovascular bundles and bone cortex.
- All dead space should be closed, and there should be adequate drainage to prevent hematoma.
- Perioperative antibiotics should be given. These procedures have a low but significant rate of postoperative infection. The risk of infection following preoperative adjuvant therapy is particularly high.

**Malignant Fibrous Histiocytoma**
- Malignant fibrous histiocytoma (MFH) is the most common soft tissue sarcoma in adults. High-grade pleomorphic MFHs are a heterogeneous collection of poorly differentiated sarcomas, many of which can be specifically classified with the application of DNA and protein analysis. It most commonly affects the lower extremity and has a predilection for originating in deep-seated skeletal muscles. The tumor usually presents as a multinodular mass with well-circumscribed or ill-defined infiltrative borders. The size and location at the time of diagnosis often correlate with the ease of clinical detection: superficial variants, presenting as dermal or subcutaneous masses, may be only a few centimeters in diameter, whereas those arising in the retroperitoneum often attain a diameter of 15 cm or more. Color and consistency vary considerably and reflect, in part, the cellular composition. Red-brown areas of hemorrhage and necrosis are not uncommon. The myxoid variant of MFH contains a predomi-
nance of grayish white, soft, mucoid tumor lobules, created by the high content of myxoid ground substance.

About 5% of MFHs undergo extensive hemorrhagic cystification termed telangiectatic transformation, leading to a clinical and radiologic misdiagnosis of hematoma. A needle biopsy can result in a benign diagnosis if only the hemorrhagic center of the tumor is sampled. For these reasons, until proven otherwise, one should assume that an underlying soft tissue sarcoma is present in any adult patient with a deep-seated hematoma that does not resolve after a few weeks, even when there is a history of trauma to that site.

The currently accepted broad histologic spectrum of MFH encompasses many variants that formerly were considered distinct clinicopathologic entities. These lesions, which had been named according to the predominant cell type, include fibroxanthoma, malignant fibroxanthoma, inflammatory fibrous histiocytoma, and giant cell tumor of soft parts. Immunohistochemical studies and electron microscopy can assist in the accurate diagnosis of a significant percentage of these tumors. The basic neoplastic cellular constituents of all fibrohistiocytic tumors include fibroblasts, histocyte-like cells, and primitive mesenchymal cells (Fig 18). Both an acute and a chronic inflammatory cell component usually are present as well. The proportion of these malignant and reactive cell elements, the degree of pleomorphism of the neoplastic cells, and the predominant pattern account for the wide histologic variances.

The histologic pattern most commonly associated with MFH is a storiform arrangement of the tumor cells, which is characterized by fascicles of spindle cells that intersect to form a “pinwheel” or “cartwheel” pattern (Fig 18). Atypical and bizarre giant cells, often containing abnormal mitotic figures, may be present. The histologic grade (almost always intermediate to high) is a good prognosticator of metastatic disease. In the myxoid variant, the second most common histologic type, the tumor cells are dispersed in a richly myxoid matrix. The less common giant cell type (malignant giant cell of soft parts) is characterized by abundant osteoclast-like giant cells that are diffusely distributed among the malignant fibrohistiocytic elements. Myxoid MFH has a more favorable prognosis than other subtypes.

We recently analyzed our data of 150 MFH lesions. Our 5-year survival rates were 74%; the distant recurrence rate was 28%; and the local recurrence rate was 19%. A local recurrence, large tumor size, deep tumors, close margins, and proximal location in the extremity were found to have a significant negative prognostic influence on survival.

Liposarcoma

Liposarcoma is the second most common soft tissue sarcoma in adults. It has a wide range of malignant potential that correlates well with the histologic classification of the individual tumor. The lower extremity is the most common site and accounts for over 40% of all cases. These tumors, particularly those arising in the retroperitoneum, can attain enormous size; specimens measuring 10 to 15 cm and weighing more than 5 kg are not uncommon (Fig 19A). Liposarcomas tend to be well-circumscribed and multilobulated. Gross features usually correlate with the histologic composition. Well-differentiated liposarcomas contain variable proportions of relatively mature fat and fibrocollagenous tissues, vary from yellow to grayish white, and can be soft, firm, or rubbery. A tumor that is soft, is pinkish tan, and has a mucinous surface probably is a myxoid liposarcoma, the most common histologic type. The high-grade liposarcomas (ie, round cell and pleomorphic) vary from pinkish tan to brown and may disclose extensive hemorrhage and necrosis.

Identification of typical lipoblasts is mandatory to establish the diagnosis of liposarcoma. This diagnostic cell contains one or more round, cytoplasmic fat droplets that form sharp, scalloped indentations on the central or peripheral nucleus. Well-differentiated liposarcomas often contain a predominance of mature fat cells and only a few, widely scattered lipoblasts. Inadequate sam-
ploring can, therefore, lead to a misdiagnosis of a benign lipoma (FIG 19B). Well-differentiated liposarcomas that arise in the superficial soft tissues have been called “atypical lipomas.” In the sclerosing variant of a well-differentiated liposarcoma, delicate collagen fibrils that encircle fat cells and lipoblasts make up a prominent part of the matrix. Treatment with wide excision and adjuvant radiation therapy is recommended only if marginal margins were achieved. We treat high-grade liposarcomas like any other high-grade soft tissue sarcoma, with neoadjuvant chemotherapy, wide excision, and adjuvant chemotherapy. Radiation therapy is indicated if wide margins were not achieved.

Synovial Sarcoma

Synovial sarcoma is the fourth most common soft tissue sarcoma. In spite of its name, this tumor rarely arises directly from a joint but, rather, arises in proximity to it, with a propensity for the distal portion of the extremities. Synovial sarcomas occur in a younger age group than do most other sarcomas: most patients are below the age of 40. Typical findings of synovial sarcoma include a painful mass, soft tissue calcifications on radiography, and a malignant tumor of the foot. The tumor typically presents as a deep-seated, well-circumscribed, multinodular, firm mass. Contiguity with a synovial-lined space is rare, and, occasionally, lymphatic spread occurs. Unlike most soft tissue sarcomas, synovial sarcomas may be present as a painless mass for a few years. Plain radiographs often show small calcifications within the mass. That finding should alert the physician to the diagnosis.

Virtually all synovial sarcomas are high grade. These poorly differentiated neoplasms usually present as ill-defined, infiltrative lesions with a soft, somewhat gelatinous consistency. The classic histologic presentation of this tumor is a biphasic pattern, which implies the presence of coexisting but distinct cell populations, namely, spindle cells and epithelioid cells (FIG 20A). The plump spindle cells, usually the predominant component, form an interlacing fascicular pattern that is reminiscent of fibrosarcoma. Within the spindle cell portion of the tumor, areas resembling the acutely branching vascular pattern of hemangiopericytoma are common. The arrangement of epithelioid cells varies, ranging from merely solid nests to distinct, gland-like structures (FIG 20B). When they compose glandular spaces, the constituent cells range from cuboidal to tall columnar; they rarely undergo squamous metaplasia. Histochemical stains demonstrate that the glandular lamina contain epithelial-type acid mucins. The neoplasm may contain extensive areas of dense stromal hyalinization, and focal calcification is common. The presence of extensive areas of calcification, sometimes with modulation to benign osteoid, deserves recognition, because this rare variant imparts a significantly more favorable prognosis than that for other forms of synovial sarcoma.

The existence of a monophasic spindle cell synovial sarcoma has been recognized, although distinguishing it from fibrosarcoma can be difficult. In contrast to fibrosarcoma, the spindle cell variant of synovial sarcoma may contain cytokeratins, as demonstrated with immunohistochemical studies.

Biopsy of Musculoskeletal Tumors

Jacob Bickels and Martin M. Malawer

BACKGROUND

- Biopsy is a fundamental step in the diagnosis of a musculoskeletal tumor. It should be regarded as the final diagnostic procedure, not as a mere shortcut to diagnosis.
- Biopsy should be preceded by careful clinical evaluation and analysis of the imaging studies. Diagnosis of a musculoskeletal lesion is based on this triad of clinical, pathological, and imaging findings, and all three must coincide. Otherwise, the diagnosis should be questioned.
- Most biopsies are technically simple to perform. Decisions regarding the indication for biopsy, the specific region of the lesion for biopsy, and the anatomic approach and biopsy technique, however, can make the difference between a successful biopsy and a catastrophe.
- A poorly performed biopsy can become an obstacle to proper diagnosis and may impede the performance of adequate tumor resection, as well as having a negative impact on patient survival.
- It has been shown that biopsies executed in a referring institution rather than in a specialized oncology center often are associated with unacceptably high rates of devastating complications, unnecessary amputations, and major errors in diagnosis.

PATHOGENESIS

- Tumors arising in bone and soft tissues share characteristic patterns of biologic behavior, stemming from their common mesenchymal origin and anatomic environment. Those unique patterns form the basis of the staging system and current treatment strategies.
- Histologically, sarcomas are categorized as low, intermediate, or high grade based on tumor morphology, extent of pleomorphism, atypia, mitosis, and necrosis. Grading represents their biologic aggressiveness and correlates with the likelihood of metastases.
- Sarcomas form a solid mass that grows centrifugally, with the periphery of the lesion being the least mature part.

Pseudocapsules

- Unlike the true capsule that surrounds benign lesions, which is composed of compressed normal cells, sarcomas usually are enclosed by a reactive zone, or pseudocapsule. This consists of compressed tumor cells and a fibrovascular zone of reactive tissue with a variable inflammatory component that interacts with the surrounding normal tissues.
- In addition, these cells may break through the pseudocapsule to form metastases (“skip metastases”) within the same anatomic compartment in which the lesion is located. By definition, these are locoregional micrometastases that have not passed through the circulation. This phenomenon may be responsible for local recurrences that develop in spite of apparently negative margins after a resection.
- Although low-grade sarcomas regularly interdigitate into the reactive zone, they rarely form tumor skip nodules beyond that area.

Compartmentalism

- Sarcomas respect anatomic borders. Local anatomy influences tumor growth by setting natural barriers to extension of the lesion. In general, sarcomas take the path of least resistance and initially grow within the anatomic compartment in which they arose.
- In a later stage the walls of that compartment (either the cortex of a bone or aponeurosis of a muscle) are violated, and the tumor breaks into a surrounding compartment.
- Most bone sarcomas are bicompartamental at the time of presentation; they destroy the overlying cortex and extend directly into the adjacent soft tissues.
- Soft tissue sarcomas may arise between compartments (extracompartamental) or in an anatomic site that is not walled off by anatomic barriers such as the intermuscular or subcutaneous planes. In the latter case, they remain extracompartamental and only break into the adjacent compartment at a later stage.
- Carcinomas, on the other hand, directly invade the surrounding tissues, irrespective of compartmental borders.
- Unlike carcinomas, bone and soft tissue sarcomas disseminate almost exclusively through the blood. Hematogenous spread of extremity sarcomas is manifested in the early stages by pulmonary involvement and in later stages by bony involvement.

DIAGNOSTIC STUDIES

- Biopsy of a musculoskeletal lesion should be performed only at the conclusion of staging, in which the imaging studies required to determine local tumor extension, its relation to adjacent anatomic structures, and presence of metastatic spread are performed. Data obtained from the staging process allow the surgeon to determine which region of the tumor represents the underlying pathology and to plan the surgical approach for the definitive resection.
- When appropriately analyzed and combined with results of clinical evaluation, these data allow accurate diagnosis in most musculoskeletal lesions prior to biopsy. Thus, lesions that appear to be benign clinically and radiologically do not need biopsies.
- In contrast, benign-aggressive, malignant, and questionable lesions do require a biopsy for confirmation of the clinical diagnosis and for accurate classification before definitive treatment is initiated.
- A final reason for deferring biopsy until staging is completed is that biopsy superimposes both real and artificial radiologic changes at the biopsy site, and these can alter the interpretation of the imaging studies.
A cut through a high-grade soft-tissue sarcoma showing its thin pseudocapsule, composed of compressed tumor cells, and a fibrovascular zone of reactive inflammatory response. B. Growth pattern of bone and soft tissue sarcomas. Sarcomas grow in a centripetal fashion, with the most immature part of the lesion at the growing edge. A reactive zone is formed between the tumor and the compressed surrounding normal tissues and may be invaded by tumor nodules that represent microextensions of the tumor (satellites) rather than a metastatic phenomenon. High-grade sarcomas may present with tumor nodules that grow outside the reactive zone (“skip” lesions) but within the same anatomic compartment in which the lesion is located. This finding is documented preoperatively in less than 5% of patients. C. High-grade sarcomas may break through the pseudocapsule to form “skip” metastases within the same anatomic compartment. Skip metastases (arrows) from an osteosarcoma of the distal femur. D. A 40-year-old woman presented with a rapidly enlarging mass that had developed in her calf. Physical examination revealed a deep-seated, firm mass, 10 cm in diameter, located at the proximal aspect of the calf. E. MRI demonstrated the primary lesion as well as two additional skip metastases in the substance of the soleus muscle. F,G. Angiograms of the lower extremity clearly show all three lesions. (B: Reprinted from Bickels J, Jelinek JS, Shmookler BM, et al. Biopsy of musculoskeletal tumors. Current concepts. Clin Orthop Relat Res 1999;368:212–219, with permission.)
FIG 2 • High-grade osteosarcomas of the distal femur (A), proximal tibia (B), and proximal femur (C) showing tumor extension to the articular cartilage, which remains intact. This phenomenon allows intra-articular resection in most cases of juxta-articular sarcomas of bone. D. Extension of an osteosarcoma of the distal femur to the knee joint along the cruciate ligaments. The articular cartilage is intact. Knee joint extension of a high-grade sarcoma of the distal femur is a rare event, necessitating extra-articular resection (ie, en bloc resection of the distal femur, knee joint, and a component of the proximal tibia), as shown here.

FIG 3 • Plain radiograph (A) and MRI scans (B,C) showing a classical osteosarcoma of the distal femoral metaphysis breaking through the medial cortex into the adjacent soft tissues. Clinical photograph (D) and plain radiograph (E) showing neglected soft tissue sarcoma of the leg eroding through the overlying skin and into the underlying tibia, causing a pathological fracture.
A. Metastatic carcinoma at the same anatomic location penetrating directly into the nerve and causing an intractable, agonizing sciatic pain. Plain radiographs show metastatic osteosarcoma to the lungs (B) and L3 (C). D. Liposarcoma of the posterior thigh extending to the sciatic nerve. Although the patient presented with sciatic pain, there was a clear plane of dissection between the tumor capsule and the nerve.

FIG 5 • Osteochondroma of the distal femur (A) and deep lipoma of the shoulder (B). These lesions have typical findings on clinical examination and classical appearance on imaging studies. Consequently, biopsy is not required for their diagnosis or for decision-making regarding their management.
SURGICAL MANAGEMENT

Preoperative Planning

- The questions that must be answered before performing a biopsy are:
  - What part of the lesion needs to be biopsied?
  - What is the safest anatomic route to that location?
- The position of the biopsy site within the lesion is of major significance, because soft tissue and bone sarcomas may have regional morphologic variations. As a result of that heterogeneity, when doing a needle biopsy, a considerable volume of tumoral tissue or multiple samples are required to establish a diagnosis.
- The term sampling error refers to an incorrect or inconclusive diagnosis that occurs because the biopsy specimen was taken from a region that does not represent the underlying primary disease.
- In contrast, carcinomas commonly are homogeneous, so a single core biopsy or needle aspirate is usually sufficient for diagnosis.
- The periphery of soft tissue sarcomas usually represents the underlying malignancy authentically, and it should be the target of biopsy. Performing a biopsy on a sample taken from the center of this type of lesion may result in ambiguous findings, because these sites may contain mostly necrotic tissue and blood.
- Similarly, the extraosseous component of a malignant bone tumor is as representative of the tumor as is the bony component, and it should be biopsied if present. Violating the cortex of a bone that harbors a malignant tumor predisposes the patient to a pathologic fracture, and is acceptable only if there is no extraosseous extension of the tumor.
- In planning the definitive surgery, it must be assumed that the biopsy tract is contaminated with tumor cells and, therefore, it should be resected with the same safety margins (ie, wide margins) as the primary tumor (FIG 6A). For these reasons, the surgeon performing the biopsy must be familiar with the planned surgical technique, whether it is limb-sparing surgery or amputation.
- The biopsy incision or the needle puncture hole and the tract to the tumor must be made within the planned surgical incision site so that they will be included within the surgical specimen (FIG 6B–F).

FIG 6 • A. Pathological evaluation of a biopsy tract, resected en bloc with metastatic melanoma of the distal humerus, showing a viable tumor focus. B. The needle biopsy entry site and tract to the osteosarcoma shown in Fig 3A–C are removed en bloc with the tumor. C. The surgical specimen. D. Planned biopsy incision around the proximal humerus. Because most primary bone sarcomas extend into the surrounding soft tissues, the overlying muscle should be removed en bloc with the tumor. In this case, the deltoïd muscle should be removed with the tumor, and the biopsy tract should be included within the surgical specimen, indicating the choice of a transdeltoid approach through the anterior third of the muscle. The traditional deltopectoral approach for such a biopsy would necessitate a wider resection of the pectoralis major muscle, compromise its subsequent use for soft tissue reconstruction, and possibly contaminate the main neurovascular bundle of the upper extremity. (continued)

BIOPSY TECHNIQUES

- A closed biopsy does not involve an incision. The specimen is obtained after skin puncture by a needle or trephine.
- An open biopsy, in contrast, does require an incision. It can be either "incisional," in which case only a representative specimen is removed from the lesion, or "excisional," in which case the lesion is completely removed.
- Open incisional biopsy remains the most reliable diagnostic technique to which all other biopsy modalities should be compared. It allows the pathologist to evaluate cellular morphologic features and tissue architecture from different sites of the lesion.
- Furthermore, it provides material for performing ancillary studies, such as immunohistochemistry, cytogenticics, molecular genetics, flow cytometry, and electron microscopy. These studies may help in the diagnosis and subclassification of bone and soft tissue tumors, and, therefore, guide the choice of definitive treatment.
- Open biopsies are criticized because of the increased risk of complications, which may include iatrogenic injury to blood vessels or nerves, complicated wound healing, wound infection, and tumor cell contamination along the biopsy tract and subsequent local recurrence. Furthermore, open biopsies are associated with considerably higher costs of hospitalization and operating room time.
- Refined techniques and accumulated experience with the interpretation of material obtained from needle biopsies as well as the use of CT-guided trephine biopsies have made possible the accurate diagnosis of most musculoskeletal lesions. Thus, guided needle biopsies have become the standard technique in most orthopaedic oncology centers.9,10
- When a needle biopsy does not make conclusive diagnosis possible, or when it is not compatible with the clinical or radiologic diagnoses that have already been made, the patient should be referred for to an open surgical biopsy rather than to repeated needle biopsy.
Guided Needle Biopsy

- After adequate planning of the biopsy tract, biopsy should be executed according to the following guidelines:
  - Use the smallest longitudinal incision compatible with obtaining an adequate specimen. Transverse incisions are contraindicated, because they will require a wider soft tissue resection at the time of definitive surgery (TECH FIG 1).
  - When a purely intraosseous bone lesion is being biopsied, make a cortical window, giving careful consideration to its shape. Clark et al.3 evaluated the impact of three types of biopsy hole shapes—rectangular hole with square corners, rectangular hole with rounded corners, and oblong hole with rounded ends—on the breaking strength of human femora. They found that an oblong hole with rounded ends afforded the greatest residual strength. They also demonstrated that increasing the width of the hole caused a significant reduction in strength, but increasing the length did not. Therefore, when the biopsy specimen must be taken from the bone, a small circular hole should be made so that only minimal stress-risers are created. If a larger window is needed, an oblong shape should be used (TECH FIG 2).
  - Obtain enough tissue and use a knife or curette to avoid crushing or distorting the specimen's texture.
  - As a general rule, culture what you biopsy and biopsy what you culture.
  - Use meticulous hemostasis. Any hematoma around a tumor should be considered contaminated. A large hematoma may dissect the soft and subcutaneous tissues and contaminate the entire extremity, making limb-sparing surgery impossible.

TECH FIG 1 • A. The smallest longitudinal incision that allows an adequate specimen to be obtained should be used. B. A transverse biopsy incision requires a longer and curved incision to allow its incorporation at the time of the definitive resection. These incisions often cross tension lines, compromise the blood supply to the myocutaneous flaps, and potentially contaminate a larger surgical field. As a result, postoperative radiation therapy, when indicated, is administered to a wider field. C. Open biopsy of a high-grade soft tissue sarcoma of the left buttock by means of a transverse incision. D. A long, curved incision was used at the time of the definitive surgery to allow adequate resection as well as subsequent closure of skin flaps. E. Axial T2-weighted MRI scan of the proximal thigh showing a high-grade soft tissue sarcoma of the adductor compartment. F. Open biopsy was done using a long transverse incision. G. Intersecting long incisions were required at the time of definitive surgery to remove the biopsy site en bloc with the tumor. All compartments of the thigh were grossly contaminated with tumoral tissue. (A: Reprinted from Bickels J, Jelinek JS, Shmookler BM, et al. Biopsy of musculoskeletal tumors. Current concepts. Clin Orthop Relat Res 1999;368:212–219, with permission.)
A tourniquet rarely is indicated for an open biopsy, because bleeding vessels cannot be observed and adequate hemostasis is hard to achieve. If a tourniquet is used, the limb should not be exsanguinated by wrapping with an Esmarch bandage, because this may propel tumor cells to the proximal aspect of the extremity. To allow hemostasis, the tourniquet must be removed before wound closure.

Use drains if necessary. The port of entry must be in proximity with and a continuation of the skin incision, not at an angle to its sides (TECH FIG 3). The drain path is considered contaminated and must be excised with the surgical specimen. Guidelines regarding the excision of the draining tract are similar, therefore, to those that apply to the biopsy tract.

**PEARLS AND PITFALLS**

- Biopsy must be preceded by tumor staging.
- Plan site and tract according to the planned incision and tract of the definitive surgery.
- Use the smallest longitudinal incision possible for an open biopsy.
- The periphery of musculoskeletal tumors is preferable to a central site for biopsy.
- Obtain enough material and avoid crushing or distorting the specimen’s texture.
- Culture what you biopsy and biopsy what you culture.
- Use meticulous hemostasis.
- When biopsy results do not match the results of clinical and radiologic evaluations, carefully reassess all three.
- Despite serious concerns regarding the potential of accelerated growth or metastatic dissemination of a malignant tumor after biopsy, there is no well-founded, objective evidence that biopsy promotes either adverse event. The real risk of open and needle biopsies is that they may spread tumor cells locally and facilitate local tumor recurrence when performed inadequately.
REFERENCES

BACKGROUND

- Limb salvage—reconstruction following resection of malignant tumors of the extremities—has seen dramatic advances in a relatively brief period of time. The traditional surgical approach to the treatment of sarcoma, namely immediate amputation of the extremity, was advocated in the early 1960s and 1970s to ensure local control of disease.
- Early pioneers in orthopaedic oncology worked diligently to define the optimal level of amputation and developed techniques to manage wounds of the pelvis and shoulder girdle following hind- or forequarter amputation. However, such aggressive surgical management failed to impact overall patient survival, with most patients dying of metastatic disease.
- Only after the introduction of effective doxorubicin- and methotrexate-based chemotherapy protocols in the early 1970s could alternatives to amputation be considered. A handful of surgeons began to challenge the orthodoxy of amputation in children and adults with bone sarcomas. Marcove, Francis, and Enneking were among the pioneers who developed the rationale and basic techniques used in limb-sparing surgery. The former two surgeons were the first in the United States to develop endoprosthetic replacements for tumor patients.
- Starting with a very few highly selected patients with extremity osteosarcoma, limb-sparing surgery now is a treatment option for most bone and soft tissue sarcomas, not only of the extremities, but of the pelvis and shoulder girdles as well.
- Today, over 90% to 95% of tumor patients may be expected to undergo successful limb-sparing procedures when treated at a major center specializing in musculoskeletal oncology. This dramatic alteration in patient care required significant advances along many fronts, including the following:
  - Better understanding of tumor growth and metastasis
  - Determination of appropriate surgical margins
  - Use of effective induction (neoadjuvant or preoperative) chemotherapy
  - Development of improved approaches, preserving soft tissue vascularity
  - Deeper understanding of skeletal biomechanics
  - Advanced material engineering and manufacturing techniques
  - Development of inherently stable modular prostheses.
- The chapters in this section outline in specific detail many of the surgical approaches and techniques of oncologic resection and reconstruction currently used by leaders in the field of orthopaedic oncology. The importance of meticulous surgical technique cannot be overstated, because this is vital to ensure an optimal oncologic and functional outcome for the patient.
- A successful limb-sparing surgery consists of three interdependent stages performed in sequence:
  1. Tumor resection with appropriate oncologic margins
  2. Reconstruction and stabilization of the involved bone and joints
  3. Restoration of the soft tissue envelope for prosthetic coverage and function.

History of Endoprosthetic Reconstruction

- Austin Moore and Harold Bohlman, in 1940, were the first to publish an example of endoprosthetic reconstruction for a bone tumor, consisting of a custom-designed Vitallium proximal femur used for a patient with a giant cell tumor of bone.
- In the early 1970s, Francis and Marcove ushered in the current age of endoprosthetic reconstruction by developing prostheses to replace the distal femur and the entire femur for reconstruction following radical resection of osteosarcomas (FIG 1).
- A major drawback for these custom implants quickly became evident: each implant would take 6 to 12 weeks to manufacture, during which time the patient’s tumor could progress significantly. This led to the development of the concept of induction (initially called preoperative or neoadjuvant) chemotherapy, in which the newly proven drugs doxorubicin and methotrexate were administered during the interval between diagnosis and delivery of the manufactured custom implant. Both of these drugs had just been shown to have activity against bone sarcomas. Induction chemotherapy has since been adopted in the management of an increasingly large variety of other cancers.
- As the demand for endoprosthetic reconstruction grew, a wide variety of custom implants became available from a number of orthopaedic manufacturers. Many of these early implants, however, suffered from design flaws and errors in manufacturing, resulting in significant problems with implant failures (FIG 2A).
- However, improved material and manufacturing techniques developed for the profitable and ever-expanding market for total joint replacements eventually were applied to these “mega” prostheses. The adoption of the rotating hinge for implants around the knee and bipolar heads for the hip followed successful use of these designs for total joint replacement. While these advances significantly improved the performance of custom implants, problems with the time required for manufacturing and the lack of flexibility at the time of implantation hampered the widespread acceptance of custom endoprosthetic reconstruction.
- Manufacturers responded to this problem by incorporating the concept of modularity, adapting concepts and designs from modular total hip and knee prostheses to develop interchangeable and easily assembled endoprosthetic systems (FIG 2B,C). Although modularity increased the complexity of the mechanical construct and carried a risk of failure associated with the sum of all of the components, these potential problems were easily outweighed by significant benefits.
- The primary advantage of a modular endoprosthesis is the system’s flexibility: the surgeon can concentrate on performing the best possible oncologic resection knowing that any changes in the preoperative plan can be accommodated by selecting those components that fit the patient’s anatomy and actual skeletal defect optimally.
Modular trial components allow the surgeon to mix and match pieces and test the reconstruction prior to selection and assembly of the actual final prosthesis.

Standardization of components permits the implant manufacturer to increase the level of quality control greatly, while reducing the overall cost of manufacturing through economies of scale.

Modular systems reduce overall inventory and time to delivery while providing a large choice of prosthetic shapes and sizes.

Modular systems permit hospitals to maintain an on-site inventory that has allowed these systems to be available immediately as a backup option for selected non-oncologic patients, such as those undergoing difficult joint revision surgery or patients with significant periarticular fractures.

A first-generation modular endoprosthetic system was the Howmedica Modular Replacement System (HMRS, Howmedica International, Limerick, Ireland), designed and manufactured in Europe. This system featured intramedullary cementless press-fit stems supported by external flanges and cortical transfixation screws, while the knee mechanism consisted of a simple hinge design. Although the system truly was modular, in clinical practice the long-term outcomes were disappointing. Significant problems encountered with this device included aseptic stem loosening (osteolysis), substantial stress shielding with bone resorption, screw fracture and migration, and a polyethylene failure rate higher than 40% for the knee mechanism. Consequently, this system rarely was used in the United States.

An example of a second-generation modular system is the saddle endoprosthesis (Waldemar-Link, Germany; FIG 3A,B). This prosthesis, originally designed for the treatment of infected failed total hip replacements, was modified to allow for reconstruction of the hip following resection of the pelvis.

The unique feature of this system is the saddle itself, which is a U-shaped component that straddles the ilium, allowing motion in flexion–extension, and abduction–adduction in the anteroposterior and lateral planes against the bone.

The saddle is attached with a rotating polyethylene lined ring, increasing the degree of freedom and allowing for hip rotation. These are attached to a series of interchangeable modular bodies that, in turn, connect to a standard cemented femoral stem.

FIG 1 • The first known distal femoral replacement was performed in the United States, by Kenneth Francis, at New York University in 1973. A, Distal femoral osteosarcoma treated with doxorubicin prior to surgical resection. B, Cemented distal femoral replacement with long intramedullary stems. This prosthesis used a modified Walldius fixed knee hinge. C, Scan of the front page of an historic JBJS article. Original publication of the first prosthesis performed in the United States. D, Original prosthesis implanted by Drs. Bohlman and Moore for fibrous dysplasia of the proximal femur. E, Custom segmental prosthesis used during 1980s prior to the development of the Modular Replacement System by Howmedica, Inc. (Rutherford, NJ). (A, B: Courtesy of Martin M. Malawer; C: reprinted from JBJS, 1940, with permission.)
FIG 2 • A. Examples of failed, retrieved, custom endo-prosthetic implants used during the 1980s. The most common mode of mechanical failure was stem breakage or bending, typically due to small stem diameter or from stress risers caused by the sharp transition from the prosthetic body to the stem. B. Modular implant design featuring a Kinematic rotating-hinge knee. Interchangeable components permit easy off-the-shelf flexibility in the operating room, allowing the implant to match the patient’s anatomy. C. Intraoperative assembly of the prosthesis requires impaction of locking Morse tapers to connect the stem, body segments, and joint modules. (Courtesy of Martin M. Malawer.)
This device preserves limb length following resection of the periacetabulum (eg, type 2 pelvic resection, modified internal hemipelvectomy) while functioning like a total hip prosthesis. The clinical and functional results following saddle reconstruction of the pelvis with this system have been promising. The first successful universal modular system was introduced in 1988 as the Modular Segmental Replacement System (MSRS, Howmedica Inc, Rutherford, NJ), renamed the Modular Replacement System (MRS) and now available as the updated Global Modular Replacement System (GMRS; Stryker/Howmedica Inc., Mahwah, NJ). This system was designed to provide modular replacements for the proximal humerus, proximal femur, total femur, distal femur, and proximal tibia and has been instrumental in the widespread adoption of endoprosthetic reconstruction following segmental bone resection.

The growing popularity of endoprosthetic reconstruction has led to the introduction of similar modular systems from several orthopaedic manufacturers (eg, Orthopaedic Salvage System [Biomet, Warsaw, IN], Guardian Limb Salvage System [Wright Medical Technology [Arlington, TN]]).

Current implant manufacturers still offer customized solutions for challenging anatomic issues. However, these custom implants often consist of a custom module mated to an existing modular system to ensure maximal flexibility.

**TYPES OF ENDOPROSTHETIC RECONSTRUCTION**

Specific anatomic examples of endoprosthetic reconstruction are discussed in the following paragraphs.

**Hip**

- Tumors involving the proximal femur are extremely common, and include both primary sarcomas and metastatic carcinomas. Replacement of the proximal femur (FIG 4) is readily accomplished following resection of a primary tumor or fracture through a subtrochanteric metastatic lesion. A bipolar hemiarthroplasty is used for the hip joint, with soft tissue reconstruction of the hip capsule to minimize the risk of dislocation. Reconstruction of the hip abductors is accomplished directly via laterally placed holes or loops, or, if a portion of the trochanter was saved, by use of a trochanteric claw with cerclage cables. Less common are resections of the entire hip joint (ie, type II pelvic resection and its modifications). This defect can be reconstructed with a saddle prosthesis or with the recently designed partial pelvic implants that attach to the remaining ilium. Stability is achieved by balancing the muscle tension between the medial iliopsoas and the lateral hip abductors.

**Distal Femur**

- The distal femur is the single most common site for primary bone sarcomas. Endoprosthetic reconstruction (FIG 5) requires a unique combination of flexibility combined with overall stability, because the knee capsule and the cruciate and collateral ligaments are removed during the resection. The Kinematic rotating hinge knee (GMRS, Stryker/Howmedica, Mahwah, NJ) and similar partially constrained hinged designs permit substantial flexion–extension as well as rotation at the anatomic axis of the knee, while providing inherent stability in the varus–valgus and anterior–posterior planes. Reconstruction of the extensor mechanism rarely is necessary, because the patella often can be saved during the resection. Resurfacing of the patella is possible, but often unnecessary.

**Total Femur**

- Patients presenting with extensive intramedullary tumors (eg, Ewing sarcoma or the rare diaphyseal osteosarcoma), as
well as patients with multiply failed total joints and little remaining bone stock, can be treated with a total femoral replacement (FIG 6). Modular systems provide a readily available solution by combining distal femoral and proximal femoral components by means of interbody segments. This type of reconstruction has proven to be extremely durable because of the combination of the high degree of freedom associated with the two separate but related joints.

Proximal Tibia
- The tibia is anatomically unique in its anterior subcutaneous border and patellar tendon insertion. Routine use of a gastrocnemius rotation flap has dramatically reduced the incidence of postoperative complications, and compound reconstruction of the tendon insertion and careful attention to postoperative rehabilitation can result in minimal extensor lag. Joint stability at the knee is ensured by using the same rotating hinge design used for distal femoral replacements (FIG 7). Meticulous soft tissue reconstruction of the extensor mechanism is crucial for the postoperative function of this prosthesis.

Proximal Humerus
- High-grade sarcomas of the proximal humerus require extra-articular resection, including the entire rotator cuff and deltoid muscles, to minimize the risk of local recurrence (FIG 8). Accordingly, ultimate functional outcome may be greatly restricted. A combination of static and dynamic suspension, including transfer of the pectoralis muscle, stabilizes the proximal humerus to the scapula, permitting painless and functional use of the elbow, wrist, and hand. Low-grade tumors can be treated with intra-articular resections; preservation of the rotator cuff and deltoid can lead to function comparable to that provided by total shoulder replacements.
FIG 5 • Distal femoral replacement. A, B. Kinematic rotating hinge mechanism featuring an all-polyethylene tibial component permits a full range of flexion, rotation, and axial motion while restraining the knee in the AP and medial-lateral planes, respectively. C. Intraoperative view of distal femoral replacement after final assembly of the components. D–E. Distal femoral and proximal tibia modular replacement system. This system permits reconstruction of several segments of various bones simultaneously if required. (A, B: Courtesy of Martin M. Malawer.)

FIG 6 • Total femoral replacement for osteosarcoma of the femur. A. Implant and trial components consist of a modular proximal femoral replacement connected to a modular distal femoral replacement of means of a male-to-male interbody segment. B. Postoperative radiograph demonstrating bipolar hip and rotating hinge joints.
Scapula

- Following scapulectomy, endoprosthetic replacement of the scapula and glenohumeral joint lateralizes the humerus and improves stability and function of the shoulder (FIG 9). New scapular designs feature a locking articulation to improve stability, while use of a large-diameter Gore-Tex (W. L. Gore Ltd., Flagstaff, AZ) vascular graft to restore a joint capsule helps to ensure optimal stability. As with proximal humeral replacement, ultimate functional outcome depends on the amount of muscle that can be preserved during the resection. Multiple muscle transfers are necessary to stabilize and power the prosthesis as well as to provide adequate coverage.

Elbow

- The elbow joint is not often affected by sarcomas or metastatic disease. Customized, hinged implants with small-caliber stems to fit the ulna can be used provided sufficient soft tissue remains to cover the prosthesis. Function depends on preservation of the biceps insertion.

Total Humerus

- As with the total femur, the total humerus implant is a combination of a proximal humeral implant and an elbow replacement. Indications for this procedure are rare, but preservation of a sensate, functional hand remains superior to any amputation prosthesis.

Calcaneus

- One case has been reported of a total calcaneal prosthesis implanted for osteosarcoma in lieu of a below-knee amputation. Ten years after surgery, the patient remained fully ambulatory without assistive devices.
Intercalary Endoprostheses

- Replacement of the central portion of a long bone following diaphyseal resection for tumor has the significant advantage of preserving the patient’s native adjacent joints in the humerus, femur, and tibia. Traditional implants limited the indication for this type of reconstruction due to the amount of remaining bone required to fix the prosthetic stems securely. Customized stems using crosspin fixation and the newer Compress fixation method (Biomet) have greatly expanded the indications for this procedure (FIG 10).

Expandable Implants for Skeletally Immature Patients

- Reconstruction of the axial skeleton in immature patients remains challenging (FIG 11). Children over 10 to 12 years of age often can be treated similarly to adults, using smaller versions of the modular prostheses, occasionally in combination with contralateral epiphysialdysis to equalize leg lengths at skeletal maturity. For children younger than 5 years, primary amputation remains the preferred solution, given the difficulty in obtaining a proper oncologic margin around the critical neurovascular bundles. Between these two age groups, reconstruction is feasible, but limb-length inequality becomes functionally disabling as the child grows. Use of implants that can be expanded multiple times during growth permits prosthetic reconstruction for these children. These custom-created implants have been used in both the upper and lower extremity with mixed results, as mechanical failures of the expansion mechanism is not uncommon. Whereas traditional expandable implants would require multiple invasive procedures to achieve expansion (with some patients undergoing 10 or more surgeries), the recently introduced custom Rephysis noninvasive expandable implant (Wright Medical Technology, Arlington, TN) features a unique method of expansion that does not require surgery.

PATIENT SELECTION FOR ENDOPROSTHETIC RECONSTRUCTION

- Appropriate patient selection for limb-sparing surgery is essential to ensure optimal outcomes. While the introduction of effective chemotherapy for osteosarcoma was a major impetus in the development of limb-sparing techniques, increasing patient survival has placed greater emphasis on functional outcome and durability of reconstruction. Patients expect solutions that address their functional, cosmetic, and psychological needs and demands, and often reject the option of amputation.

- Although tumor size and location often are the determining factors in selecting patients for limb salvage, neoadjuvant (preoperative) chemotherapy may convert formerly unsalvageable
patients to candidates for limb-sparing procedures by inducing significant tumor response. Consequently, a complete reevaluation of the patient following neoadjuvant treatment is necessary before an appropriate surgical plan is selected. For appropriate patients, endoprosthetic reconstruction offers a durable and functional option for skeletal reconstruction.

- Limb-sparing procedures should not be limited to patients with favorable response to treatment. Patients with poor prognostic factors, such as metastatic disease at time of initial presentation or tumor growth during chemotherapy, often require surgery for local control of disease and palliation of symptoms such as pain. Although amputation may be necessary for some, limb-sparing surgery can avoid the significant psychological impact associated with mutilative procedures. Endoprosthetic reconstruction offers immediate stability and rapid mobilization while avoiding the need for prolonged bracing, crutches, or inpatient rehabilitation.

- The proven success and durability of endoprosthetic reconstruction has led to its adoption for other challenging, nontumorous conditions in which restoration of a segmental skeletal structure is desired.
tal defect is required. For example, patients with multiple failed total joint replacements around the hip and knee may develop significant bone loss that cannot be corrected readily with traditional revision total joint components. In this subset of patients, resection of the failed prosthetic joint and removal of all devascularized bone followed by reconstruction with a “tumor” endoprosthesis can lead to significant functional recovery.

- Similarly, severely comminuted periarticular fractures not amenable to internal fixation can be addressed by removal of the fragmented bone and replacement with a segmental endoprosthesis. This procedure is extremely valuable for the obese, elderly patient with osteoporotic bone (often with significant medical comorbidities) who trips and falls on the knee, resulting in a type C distal femur (or, if a total knee replacement is in place, periprosthetic) fracture. Endoprosthetic reconstruction can be performed in a fraction of the time necessary for meticulous internal fixation, and since the prosthesis is inherently stable, the patient can begin immediate weight bearing without functional bracing.

**GUIDELINES FOR ENDOPROSTHETIC RECONSTRUCTION**

- Regardless of the anatomic location, certain basic principles apply to all endoprosthetic reconstructions. Restoration of the normal axis of motion and extremity length depends on component selection. Careful attention to implant size and soft tissue reconstruction also can optimize functional outcomes. Proper stem selection, bone preparation, cementation technique, and use of extracortical fixation can reduce the risk of aseptic loosening and maximize implant longevity.
- Following resection of a bone tumor, careful measurement of the specimen is necessary to select the desired implant length. Trial components, available with all modular systems, permit easy comparison with the specimen and permit multiple trial reductions to determine optimal length and positioning for the final implant.
- Meticulous preparation of the intramedullary canal is done for stem insertion. Selection of the stem diameter depends on the anatomy of the canal, which should be sequentially reamed so that it can accommodate the largest diameter stem possible.
- Tendon and soft tissue reconstruction is determined by the anatomic site and the amount of residual tissue following tumor resection. Again, functional outcome can be enhanced with meticulous attention to details and restoration of proper biomechanics.
- Rotational muscle flaps often are necessary to ensure adequate soft tissue coverage and also may serve to reinforce tendon attachments or capsular tissue.
- Frequently performed transfers include the following:
  - **Shoulder.** Transfer of the pectoralis major and latissimus dorsi muscles covers and dynamically stabilizes a proximal humeral prosthesis. Dacron tapes are used to suspend the prosthesis statically from the scapula.
  - **Hip.** Transfer of the psoas and external rotators is performed to create a pseudocapsule around the prosthetic head. This capsule then is reinforced with circumferential Dacron tapes to prevent dislocation. Reattachment of the abductor muscles is necessary to minimize the Trendelenburg lurch in the postoperative phase. This limp improves over time with strengthening of the abductors.
  - **Knee.** Twenty-five percent of distal femoral replacements and all proximal tibial replacements require rotation of a gastrocnemius muscle (typically the medial head) to repair the soft tissue defect following resection of a tumor around the knee. In addition, this local flap is incorporated into the reconstruction of the patellar tendon for proximal tibial replacements.
- Final closure of the wound may be jeopardized by skin loss following resection of a biopsy tract. In general, patients with very large tumors often have redundant skin because the tumor has acted as an internal skin stretcher. This extra skin may be rotated or trimmed as needed to facilitate wound closure. Excess skin along the incision should be excised to avoid marginal wound necrosis related to disruption of the microvasculature from elevation of large subcutaneous flaps. Patients with tight skin closures are best served by leaving the skin open to avoid pressure-induced ischemia, and performing a primary or secondary split-thickness skin graft.
- Limbs should be elevated maximally in the postoperative phase to reduce swelling that can jeopardize the wound closure.
- Use of large-bore closed suction drains and correction of any postoperative coagulopathies help prevent hematoma formation. Patients who develop hematomas or wound breakdowns require aggressive treatment in the operating room to prevent secondary infection of the endoprosthesis.

**CLINICAL RESULTS FOLLOWING ENDOPROSTHETIC REPLACEMENT**

- Prosthetic survival has improved dramatically as improved surgical techniques, advanced prosthetic designs, and modern manufacturing techniques have been adopted. Results of early custom prostheses were disappointing, leading many surgeons to use allografts or other methods of reconstruction.
- More recently, there has been increased interest in endoprosthetic reconstruction as multiple centers have reported improved outcomes. Informal polling of members of the Musculoskeletal Tumor Society has shown a significant swing from a majority of members using primarily allograft reconstructions to a majority of members using endoprosthetic reconstruction.
- Recently published results looking at long-term survival of 242 cemented endoprosthetic replacements demonstrated an overall survival of 88% at 5 years and 85% at 10 years (Table 1). Prosthetic survival varied by type and location, with the poorest survival seen in patients with early custom-designed implants and in patients with proximal tibial replacements. Infection was the single most common cause of implant failure, with infected patients having an 83% risk of implant failure (FIG 12).
- Functional results vary by implant location. Outcomes following reconstruction of the distal femur in 110 patients were judged as good to excellent in 85% of patients.

**COMPLICATIONS**

- Complications following any type of limb-sparing reconstruction are not uncommon. Most patients have depressed immune systems from chronic disease, chemotherapy, and malnutrition. Patients often are anemic and have clotting abnormalities, including thrombocytopenia. The presence of long-term indwelling catheters for the administration of
Chemotherapy may lead to unrecognized bacteremia and potential hematogenous seeding of the operative site.

The anatomic location of a tumor and necessary resection may result in significant disruption of the venous and lymphatic drainage of the extremity during resection, leading to venous stasis, swelling, and lymphedema. This can lead quickly to flap necrosis during the postoperative period, secondary infection, and eventual amputation.

Finally, oncologic complications, including local recurrence of tumor or tissue necrosis from radiation, may result in failure of a limb-sparing procedure.

Complications specific to endoprosthetic reconstruction may be related to mechanical or biologic factors. Prosthetic fracture, disassociation of modular components, fatigue failure, and polyethylene wear have been described. Improved implant designs, metallurgy, and manufacturing techniques can reduce the incidence of these problems significantly.

Our institutional experience with more than 200 MRS (Materials Research Society, Warrendale, PA) implants over the past 18 years have revealed no stem fractures, body fractures, or taper disassociations to date. Polyethylene bushing failure occurs in fewer than 5% of patients with the Kinematic rotating hinge mechanism (Howmedica, Rutherford, NJ).

Biologic failure of an endoprosthesis may occur as a result of joint instability, aseptic loosening, or periprosthetic fracture of bone around the prosthesis. Meticulous attention to soft tissue reconstruction has virtually eliminated joint instability as a problem. The use of circumferential porous coating, properly sized large-diameter stems, and third-generation cementation techniques has helped to prevent aseptic loosening in our patients. Surgical technique and the use of polished cemented stems have prevented periprosthetic fractures during surgery. Several patients with secondary, late fractures as a result of blunt trauma (eg, falls, auto accidents) have been treated successfully with casting and protected weight bearing.

**FUTURE TRENDS FOR ENDOPROSTHETIC RECONSTRUCTION**

Current modular endoprosthetic reconstruction has greatly facilitated limb-sparing surgery following resection of bone sarcomas. Its success also has expanded the indications to include bone defects for non-oncologic problems. Increasing experience in the salvage of failed total joint replacements, chronic nonunions of fractures, and reconstruction following radical resection of osteomyelitis has shown that the proven

*Failure was defined as implant removal for any reason; patients were censored at time of last follow-up or at time of death. DF, distal femur; MRS, Modular Replacement System; PF, proximal femur; PH, proximal humerus; PT, proximal tibia.
concepts of limb-sparing surgery can be applied to many different clinical situations. Today, more endoprosthetic reconstructions are performed for non-oncologic reconstructions than for osteosarcomas.

- Ongoing research continually strives to improve the outcome following endoprosthetic reconstruction. Continued work on improved metallurgy and polymers, particularly with the introduction of cross-linked polyethylene, promises improved long-term durability. Routine use of premixed antibiotic cement and experimentation with antimicrobial implant surfaces may help to reduce the risk of periprosthetic infection. New techniques for tendon attachment to the prosthesis include novel clamps and ingrowth surfaces to promote improved junctional strength.

- New implant technologies such as the Rephyisis noninvasive expandable prosthesis offer hope to younger children with few alternative options. New fixation methods, including hydroxyapatite stems with porous coated surfaces, may be of great value in non-oncologic patients.

- The recently introduced Compress system represents the first new method of prosthetic fixation in decades. We have already adapted this system to expand the applicability of intercalary endoprosthetic reconstruction. Although future advances in tissue engineering hold the promise of artificially engineered living bone, we expect that endoprosthetic reconstruction will remain the preferred choice of orthopaedists for many years to come.

**REFERENCES**

BACKGROUND
- The two most common primary malignant bone tumors, osteosarcoma and Ewing sarcoma, are principally diseases of childhood and adolescence, with 45% of patients under the age of 16 and 17% under the age of 12 years at diagnosis.
- In the last 30 years the 5-year survival rate has increased from 10% to 70%. Even in patients with metastases at diagnosis, the 5-year survival rate has reached 20% to 30% due to chemotherapy and surgery for metastases as well as the primary tumor.
- Bone tumors in children occur predominantly in the metaphyseal region, close to the growth plate, so that sacrifice of a major physis often is necessary when the tumor is excised.
- Children who have primary bone sarcoma often require chemotherapy, which may have a subsequent suppressive effect on bone growth.
- Limb salvage surgery for bone tumors in the immature skeleton creates unique problems.
  - Maintenance of limb length after resection of one or more major growth plates
  - High functional and recreational demands of young patients, which require a durable reconstruction
  - At the knee, a constrained endoprosthesis is required (most commonly a fixed or rotating hinge implant), making it necessary for the prosthesis stem to breach the physeal plate on the side of the joint opposite to the tumor.
  - Reconstruction with expandable endoprostheses allows the maintenance of limb length equality, allows early weight-bearing, results in predictable function, has a low risk of early complications, and is readily available.
  - Disadvantages include the expense of the prostheses and the complications that are expected to increase with time in surviving patients.

ANATOMY
- About 60% to 70% of lower limb growth occurs around the knee (distal femur and proximal tibia physis), and about 80% of total growth of the humerus occurs in the proximal physis of the humerus.
- Terminal branches of the diaphyseal nutrient artery form tight loops near the physis, and the epiphysis is invaded by juxta-articular vessels.
- During childhood, the physis becomes an avascular structure that lies between two vascular beds, one epiphyseal and the other metaphyseal.
- The epiphyseal vessels supply oxygen and nutrients; an intact epiphyseal vasculature is essential, therefore, to sustain the chondrocytes. The metaphyseal vessels interact with the physeal chondrocytes in the hypertrophic zone and must be intact to sustain normal ossification. Excessive periosteal stripping must be avoided at surgery to maintain subsequent growth.

INDICATIONS FOR USE OF AN EXPANDABLE ENDOPROSTHESIS
- When the estimated leg-length discrepancy at skeletal maturity is more than 3 cm or when the arm-length discrepancy is more than 5 cm
- When the estimated arm length discrepancy at skeletal maturity is less than 5 cm, a prosthesis made up to 2 to 3 cm longer can be inserted. The operated upper limb initially is longer, but the opposite limb soon catches up.
- The main problem with a slight arm-length discrepancy is cosmetic.
- Problems with bimanual tasks occur only when the difference is significant.
- Patients whose estimated leg-length discrepancy is less than 3 cm can be treated with conventional “adult-type” prostheses made longer by up to 1.5 cm, and a “sliding” prosthetic component can be used across the remaining open physis.
- Girls older than 11 years or boys older than 13 years rarely require expandable prostheses, because the estimated growth discrepancy after these ages is less than 3 cm (FIG 1).

IMAGING AND OTHER STAGING STUDIES
- Pediatric patients with suspected malignancy require the usual staging imaging studies (ie, plain radiograph and MRI scan of affected bone, chest CT scan, and isotope bone scan).
- In addition, they require:
  - Measured full-length radiograph of the affected and contralateral limb (FIG 2)
  - Hand radiograph to estimate bone age based on Greulich and Pyle’s atlas
- The estimated limb length discrepancy at skeletal maturity traditionally has been estimated using the charts devised by Andersen and Green14 or Pritchett14,15 for upper and lower extremities.
- Recently, the validated multiplier method has been shown to be a simple and accurate predictor of discrepancy. It can be computed using chronologic, not bone, age, and requires only a single measurement.

SURGICAL MANAGEMENT
- In our center, the most common sites for the use of expandable endoprostheses are the distal femur (52%), proximal tibia (24%), proximal humerus (10%), and proximal femur (6%).
- Surgical techniques for excision of the sarcoma are similar to those for adult tumors, which are discussed in later chapters (see Chaps. ON-8, ON-10, and ON-24–26). This chapter deals primarily with factors that must be considered with the use of expandable prostheses.
We currently use two main methods of lengthening expandable endoprostheses in our center. Their advantages and disadvantages are outlined in the following paragraphs (Table 1):

- The minimally invasive expandable prosthesis has been in use since 1993. It is lengthened using a worm drive mechanism (FIG 3A,B). The mechanism is encased within the prosthesis shaft, and the telescopic implant is extended using an Allen key. The operative technique for lengthening is described later in this chapter.

- The noninvasive expandable prosthesis has been in use since 2002. Surgery is not required to lengthen the prosthesis. A sealed motor unit inside the prosthesis contains a powerful magnet that can be activated by an external power source (eg, a rotating electromagnetic field). This causes the magnet to turn, and the motor works using a very-low-ratio gearing system (13061:1) to lengthen the prosthesis. The rate of lengthening is directly proportional to the length of time that the power source is applied: lengthening of 4.6 mm takes 20 minutes (FIG 3C–E).

- The physis on the opposite side of the joint can be either preserved using a “sliding” prosthesis or sacrificed and replaced with a fixed cemented prosthesis.

- The sliding component is an uncemented, smooth component placed through a canal made centrally in the remaining preserved physis. In larger children, it is fitted inside a plastic sleeve inside the bone, which acts as a centralizer.

- This sleeve allows the component to slide inside the bone as the remaining open physis grows (FIG 3F–G).

- Care must be taken to minimize damage to the proximal growth plate by avoiding excessive periosteal stripping and carefully drilling out a cylindrical hole in the bone and, preferably, the center of the physis.

- Insertion of the sliding component destroys no more than 13% of the growth plate in the distal femur and proximal

FIG 3 • Minimally invasive prosthesis showing the port used for lengthening (A) and demonstrating the worm drive mechanism (B). C. Internal design of the shaft of the JTS noninvasive prosthesis (Stanmore Implants Worldwide). D. Gearbox and magnet component of a noninvasive prosthesis. E. Patient undergoing lengthening using an electromagnetic coil. Lengthening of 4.6 mm will take 20 minutes but can be done in the outpatient department. F. Schematic illustration of a sliding component in the proximal tibia. The proximal tibial physis is preserved, and the uncemented smooth prosthesis slides within the polyethylene sleeve as the physis grows. G. Illustration of the amount of growth of the proximal tibial physis 6 years after a distal femoral replacement with a sliding tibial component. The amount of growth can be seen by the growth arrest line formed at the time of chemotherapy. Growth on the affected side is only slightly less than that on the normal side. H. The use of hydroxyapatite-coated collars has been shown to reduce the rate of aseptic loosening by encouraging bone ongrowth.
tibia. There is no correlation between the surface area destroyed and continued growth of the physes.14,7
- Animal models of transphyseal pediatric anterior cruciate ligament reconstruction have shown similar results.2
- Physes with “sliders” grow at a slower rate, achieving about 80% of normal growth in the proximal tibia and about 60% of normal growth in the distal femur compared with the contralateral limb4 (Fig 3G).
- Other methods of lengthening prostheses are in use worldwide.
  - A device developed by Kotz allows the prosthesis to be lengthened by a ratchet system that uses knee movement to cause it to lengthen.9
  - The Phenix system (Phenix Medical, Paris, France) is a noninvasive system that relies on a coiled spring located inside the prosthesis, contained within a shield of wax. When a power source is applied to the prosthesis, the wax melts and the spring extends. When the power source is removed, the wax solidifies and the spring is fixed in its new position.12
  - The following factors are important when using expandable prostheses:
    - Resect the tumor with a wide margin and divide the bone at the predetermined level of transection.
    - When an expandable replacement is being used, plan to replace the exact amount of bone that has been removed.
    - If cement is being used, the intramedullary canal must be prepared adequately. We advocate the use of antibiotic-impregnated cement.
    - The use of hydroxyapatite-coated collars and preservation of periosteal sleeve significantly reduces the long-term risk of aseptic loosening by encouraging bony ingrowth to the prosthesis and also avoids the risk of stress shielding seen in uncemented types of implants (FIG 3H).

Preoperative Planning
- Calculate estimated limb-length discrepancy at skeletal maturity
  - Allow for reduced growth from any growth plates disturbed by surgery.
  - Consider whether there any surgical options other than an expandable prosthesis are feasible. These include:
    - The use of a shoe lift if the difference is less than 2 cm
    - Inserting an adult prosthesis (with or without a sliding component) longer than the resected bone at the time of initial surgery.
- Planned epiphyseodesis of the opposite limb
- Decide whether to use an invasive or noninvasive prosthesis, based on factors described previously (Table 1)
- Accurate measured radiographs of the bones to be resected are sent to the engineers, together with clear information about the planned level of transection of the bone (from MRI scan or, in complex cases, cross-sectional imaging of the resection level).
- Screen and treat patients for potential infective foci: dental hygienist review; methicillin-resistant Staphylococcus aureus (MRSA) screening; inspection for common sites of infection such as central venous lines, throat, ingrowing toenails, and fungal skin infections.
- Ensure adequate neutrophil and platelet counts prior to surgery if patient has had recent chemotherapy (our unit requires a neutrophil count greater than 1000/mm³ and platelet count of 75,000/mm³ or higher).

Positioning
- Positioning is chosen according to the usual technique and approach that the surgeon is familiar with for adult prostheses.
- We favor double skin preparation with chlorhexidine followed by an alcohol-based solution. The limb should be draped in such a way as to be left free and mobile during the procedure.
- The standard positions we use for common sites of reconstruction are as follows:
  - Distal femur: supine with removable sterile leg support
  - Proximal tibia: supine with removable sterile leg support
  - Proximal humerus: “beach chair” position, with arm supported on small side table and head turned away supported on head ring
  - Proximal femur: Lateral position

Approach
- Resection of the tumor should be carried out by the usual technique and approach that the surgeon is familiar with for adult prostheses.
- We favor an anteromedial approach to tumors around the knee. We routinely open the knee joint and reflect the extensor mechanism laterally unless there is evidence of frank knee joint invasion (which is a relative contraindication to limb salvage).
- If the knee joint is involved, consider an extra-articular resection if sufficient soft tissue will be left to cover the prosthesis.
- For tumors around the hip we favor a direct lateral approach and for tumors of the proximal humerus we favor the expansile approach of Henry.

SURGICAL TECHNIQUE FOR IMPLANTATION OF EXPANDABLE PROSTHESES

- Surgical technique for the implantation of expandable prostheses is described for each common anatomic site—in greater detail for the distal femur, but with only the salient specific points for each of the other sites.

Distal Femoral Expandable Prosthesis
- Tumor is excised at a predetermined level via an anteromedial incision and medial parapatellar approach, preserving a short periosteal sleeve to cover the hydroxyapatite collar to promote bony ongrowth to the prosthesis (TECH FIG 1).
TECH FIG 1 • Operative technique series for the distal femur. A. MRI scan of distal femoral osteosarcoma. Although the tumor appears to stop short of the physis, subperiosteal extension is present below the physis. The proximal limit of tumor will be more clearly visible on T1-weighted images. B. Anteromedial approach to the distal femur, showing excision of the biopsy tract and incision of the tendon of the rectus femoris. C,D. Dissection through the knee joint, dissecting the popliteal vessels from the posterior femur. E. Resected tumor with components. F. Tibial plateau resected 10 mm below joint line and perpendicular to the ankle joint. A central hole is reamed carefully to accept a sliding component. G,H. A polyethylene sleeve is inserted, uncemented, into the tibial plateau, and the metallic stemmed tibial implant is trialled. I. The distal femoral component is cemented into place and the two prostheses secured with the bushes. J. The range of flexion is tested on the table. K. The resected specimen showing the extent of the tumor, with closest margin indicated by the inked circle. Following neoadjuvant chemotherapy 98% of the tumor was necrotic.
A bone marrow sample is sent from the resection level for histologic review.

The proximal femoral canal is prepared using flexible reamers, bushes, irrigation, and cement restrictors, as appropriate.

The tibial osteotomy should be done perpendicular to the long axis of the tibia so as to be parallel with the ankle joint, removing 1 cm of bone from the proximal tibia.

Great care must be taken to minimize damage to the proximal growth plate by avoiding excessive periosteal stripping and carefully drilling out a cylindrical hole in the bone, of sufficient size to accept the intramedullary stem, which is then inserted uncemented into the bone.

In some cases a plastic tube is placed inside the bone to allow the stem to be centralized and to encourage sliding. This sometimes causes the stem to take a different path from that previously reamed; in such cases, the stem should be retrialed.

A trial reduction should be performed to check the soft tissue tension, because acute over-lengthening may cause neurologic impairment and fixed flexion deformities, with subsequent stiffness.

Once the prosthesis is cemented into place, the site of the screw mechanism can be marked on the skin by a stab incision, to make subsequent percutaneous lengthening easier if a minimally invasive prosthesis is being used.

The skin is closed in layers over a drain, and dressings are applied.

**Proximal Tibial Expandable Prosthesis**

The proximal tibia is a challenging site for limb salvage, with an above-average incidence of complications.

The tumor is excised in a manner similar to that used with adult prostheses, with thick fasciocutaneous flaps to prevent skin necrosis.

The distal femur is cut to accept the prosthesis, avoiding excessive periosteal stripping.

A central drill hole is made carefully to accept the sliding component and distal femoral stem.

The medial gastrocnemius muscle is mobilized on a pedicle based on the medial saphenous artery, and is used to cover the prosthesis and sutured to the anterior muscles.

The tibial implant is cemented into place, and the sliding femoral component is inserted.

The medial gastrocnemius flap replaces the extensor mechanism. Some surgeons have advocated using Dacron grafts attached to the prosthesis and the patella tendon.

**Expandable Prosthesis for the Proximal Humerus**

Resection of the proximal humerus leaves a weak shoulder and rotator cuff but functioning elbow and hand.

If there is a well-innervated deltoid, the humeral replacement head can be placed deep to it.

If the deltoid is damaged in any way, we often use Mersilene mesh (Ethicon Inc, Somerville, NJ) to provide a false capsule extending from the edge of the glenoid around the humeral head to prevent upward subluxation. Other authors have advocated using a polyethylene terephthalate (Trevira) tube to allow soft tissue attachments to prostheses. Attempts are made to preserve the coracoacromial ligament to reduce the risk of proximal subluxation with lengthening.

Care must be taken to prevent proximal migration of the humeral head when carrying out lengthening procedures.

**Proximal Femoral Expandable Prosthesis**

Inserting an expandable prosthesis into the proximal femur is a challenge, because the hip abductors must be detached from the greater trochanter.

They can be reattached to the fascia lata with the leg in slight abduction, which results in reasonable abduction power.

The type of femoral head to use is the subject of ongoing debate.

Uni- or bipolar femoral head replacements are used most frequently.

Both have high failure rates, with a significant risk of late head subluxation in children.

Small-sized femoral heads have a significant risk of dislocation.

Consider a large bearing total hip arthroplasty once the patient has reached skeletal maturity. We currently favor a large bearing metal-on-metal articulation for the increased wear characteristics and reduced dislocation rates.

**Percutaneous Lengthening for Minimally Invasive Prostheses**

The patient is placed in the supine position with access to the lengthening port.

In older children, the lengthening can be performed under a local anesthetic, but general anesthesia is preferred in younger children.

The procedure is performed under radiographic control to keep the incision as small as possible.

After double skin preparation and intravenous antibiotic prophylaxis, a stab incision is made over the jack point down to the prosthesis cavity.

The jack point is identified radiologically, and the Allen key engaged into the mechanism.

Soft tissue occasionally may need to be cleared from the jack point with a small periosteal elevator.

The screwdriver is rotated to lengthen the prosthesis: 10 revolutions of the screw driver lengthen the prosthesis by 0.1 cm; therefore, 100 revolutions are required to lengthen by 1 cm.

Intermittent single-shot images are taken to confirm lengthening.

Most lengthening procedures are done 10 mm at a time. If lengthening of much more than this is attempted, it can lead to complications such as the development of a fixed flexion deformity or occasionally a neuropraxia (eg, a foot drop).
POSTOPERATIVE CARE

- We advocate 24 hours of intravenous broad-spectrum prophylactic antibiotics postoperatively.
- We advocate early removal of surgical drains (within 48 hours).
- Patients with distal femoral replacements:
  - Are allowed to mobilize partial weight bearing at 48 hours
  - Are begun on both active and passive knee exercises
  - Usually can achieve active straight leg raise by day 5 and knee flexion to 90 degrees within 10 days prior to discharge.
- Patients with proximal tibial replacements:
  - Are allowed to mobilize partial weight bearing at 48 hours but can wear an extension brace to protect the extensor mechanism for 4 weeks
  - During that time they are allowed to flex to about 45 degrees but are not permitted to perform active knee extension.
- Patients with proximal femoral replacements are kept on bed rest with the leg abducted for 5 to 7 days before getting up, after which they are permitted partial weight bearing for 6 weeks.
- Patients with humeral replacements are kept in a sling for 6 weeks but with active exercises of the elbow, wrist and hand.
  - At 6 weeks, all patients start intensive physical therapy and hydrotherapy, at which time they commence full weight bearing and active exercises to maximize functional recovery.

Patient Information

- Warn patients that they have an artificial implant, which can fail.
- Caution them to avoid contact sports.
- Walking, swimming, cycling and other non-contact sports are encouraged.
- Any infective process in the body can lead to infection of the prosthesis, and early treatment with antibiotics is recommended
- Antibiotics for prophylaxis during dental procedures is required only if infection is present.
- Patients with noninvasive endoprostheses cannot have an MRI scan.

OUTCOMES

- Over the past 30 years our unit has operated on 615 children under the age of 16 with primary malignant bone tumors.
- 74 patients (12%) required amputation and the remainder (408 patients) had limb salvage using a prosthesis.
- Of the 176 patients with an expandable prosthesis, 117 are still alive and 89 have reached skeletal maturity.
- 60 patients never had a lengthening procedure carried out, either because they developed recurrent disease (metastases or local recurrence) or a complication such as infection.
- 116 patients had one or more lengthening procedures, with a mean of 5.3 lengthening procedures per patient (range 0–17 procedures) with an average total length increase of 32 mm (range 0–120 mm).
- Nineteen patients needed an amputation, either because of local recurrence (11 cases) or infection (8 cases).
- The overall limb salvage using Kaplan Meier survival curves was 83.9% at 20 years from insertion.
FIG 4 • A,B. Aseptic and rotational loosening in the distal femur after 14 years. C. Acute shortening due to displacement of a lengthening ring medially, which required revision to an adult prosthesis. D. Hip subluxation has been a problem in young patients receiving proximal femoral replacements.
COMPLICATIONS

Infection
- Deep prosthetic infection is a major concern in children who have expandable prostheses because of the need for multiple operative procedures.
- The cumulative risk of infection in our series was 21% at 10 years.
- It was related to site (proximal tibia) and previous highly invasive prosthesis designs.
- The use of gastrocnemius flaps and minimally invasive implants has reduced the infection rate to 8% at 10 years.
- The risk of infection has decreased from 3% per lengthening to about 1% with minimally invasive prostheses.
- Noninvasive prostheses should decrease the risk of infection over time.

Loosening
- The use of hydroxyapatite collars has significantly reduced the incidence of aseptic loosening. Revision usually is fairly straightforward, and the prosthesis is changed to an adult model (FIG 4A,B). Always consider the possibility that the loosening may be caused by low-grade infection.

Unplanned Shortening or Lengthening
- An unusual complication due to mechanism failures, which usually requires revision of the implant (FIG 4C)

Stiffness
- Stiffness is a common problem in younger children with prostheses around the knee, or if the prosthesis inserted is longer than the resected bone to try to gain some extra length. In some children, excessive scar tissue builds up around the prosthesis; in such cases, removal of the scar tissue can be helpful, combined with intensive physical therapy. In cases of fixed flexion deformities, intensive physical therapy, including the use of serial plaster casting, may be useful.

Subluxation of Hip or Shoulder
- Subluxation at the shoulder can be reduced by the use of Mersilene mesh. Femoral head subluxation is far more of a problem in younger children with proximal femoral replacements. We have found that in children under age 12 there is an increasing tendency for the superior margin of the acetabulum not to develop properly, and in these children the femoral head will sublux. We have tried several techniques to prevent subluxation, without success, and now revise the unipolar head to a large bearing surface uncemented cup when the triradiate cartilage is fused or subluxation is apparent (FIG 4D).

Outgrowing the Available Extension
- The maximum lengthening available in a prosthesis is 120 mm, but in many cases less than that is needed. Revision usually involves replacing only one component of the prosthesis.

Implant Breakage
- Implant breakage is rare in patients who have reached maturity with a child’s prosthesis still in place. The most common site for a fracture is at the junction of the thinner lengthening portion with the main component. Revision is required in all cases.

Periprosthetic Fractures
- Periprosthetic fractures are rare, but there does seem to be an increased risk of femoral fractures above a sliding femoral prosthesis used in conjunction with a proximal tibial growing prosthesis.

REFERENCES
BACKGROUND

- The skeleton is the third most common site of metastatic disease, after the lungs and liver. Prostate, breast, lung, kidney, and thyroid cancers account for 80% of skeletal metastases. The prolonged survival with disease of increasing numbers of cancer patients has led to growing numbers of patients with metastatic bone disease (MBD). The exact incidence of bone metastasis is unknown, but it is estimated that in the United States alone 350,000 people annually die with bone metastases.

- MBD is a major factor contributing to deterioration of quality of life in patients with cancer. These patients may require surgical intervention for the management of impending or current pathological fractures or for the alleviation of intractable pain associated with a locally progressive lesion.

- Those skeletal crises are associated with a considerable loss of function, pain, and the associated impairment of quality of life. Surgery also may be performed to remove a solitary bone metastasis with the intent of improving long-term survival in selected patients, but other than this rare exception, these surgical interventions are primarily palliative and are aimed at achieving local tumor control, structural stability of the surgically treated site, and restoration of normal function as quickly as possible. Failure to achieve one of these goals usually necessitates a second surgical intervention, and this is associated with additional impairment of an already compromised quality of life.

- Reports show failure rates of surgeries performed for MBD as high as 40%, occurring as the result of a poor initial fixation, improper implant selection, or progression of disease in the operative field.

- An attempt to treat a pathological fracture as one would treat a traumatic fracture will fail, in most cases, because the underlying disease impedes the fracture healing process. The prognosis for union of a pathological fracture also is determined to some extent by the tumor type: fractures associated with metastatic adenocarcinomas of breast and prostate, multiple myeloma, and lymphoma are much more likely to unite successfully than are those associated with malignancies of the lung, kidney, and gastrointestinal tract.

- Furthermore, even when healing does occur, it does so after an unreasonably long period of time and is of less than satisfactory quality. Reduction and immobilization used in the management of traumatic fractures are, therefore, not applicable in the management of pathological fractures due to MBD.

- Gainor and Buchert analyzed 129 pathological fractures and found that the long bone fractures that healed most predictably were those that had been internally fixed and irradiated and were in patients who survived for more than 6 months postoperatively.

- Similar observations were made by Harrington et al. Cemented hardware or prostheses are used preferentially for fixation to achieve immediate stability, and reconstruction techniques that rely on a biologic process of bone healing (eg, autologous bone grafts, allografts, or allograft-prosthetic composites) are inappropriate for the surgical management of MBD. 

INDICATIONS

- Existing pathological fracture
- Impending pathological fracture
- Intractable pain associated with locally progressive disease that had shown inadequate response to narcotics and preoperative radiation therapy
- Solitary bone metastasis in selected tumor types
- Surgical intervention for MBD is appropriate for patients who are expected to survive for more than 3 months. Patients who are expected to survive for less than 3 months are less likely to benefit from an operation, because they usually do not have the physical strength required for rehabilitation or the time needed for its completion. Those patients are treated with nonoperative approaches, such as sling and arm brace for the upper extremities or protected weight-bearing for the lower extremities.

IMAGING AND OTHER STAGING STUDIES

Plain Radiography

- Plain radiographs and CT scans of the affected site should be done, as well as plain radiographs of any additional site in which the patient reports joint or bone pain. The combined results of these studies will define the extent of bone destruction and soft tissue extension.

- If the investigated metastasis is located in a long bone, plain radiographs of reasonable quality of its entire extent should also be obtained to exclude additional metastases, because these data are crucial for surgical planning. Missed metastases could cause pathological fractures on postoperative weight bearing and require an extensive surgery for their repair.

- Chest radiographs also should be done routinely as a screening study to rule out lung metastases, considering that the lungs may be involved in most common cancers. Table 1 summarizes the list of recommended studies for patients with bone metastasis whose primary site of disease is unknown.

Bone Scan

- A total body bone scintigraphic evaluation using technetium Tc 99m (99mTc)-MDP should be done prior to any surgical intervention. This examination provides information for staging of the entire skeleton in the case of additional metastases and also can detect metastases that may require simultaneous surgery. Bone scanning is highly sensitive for bone pathology. Tracer uptake, however, is not specific for MBD and may display spuriously a large variety of inflammatory, infectious, post-traumatic, and other benign conditions. Therefore, plain radiography also should be done of any positive site on bone scan.
Bone scanning is not a substitute for plain radiographs of the entire affected bone or other sites with bone pain, because some tumors (e.g., multiple myeloma, metastatic melanoma, thyroid carcinoma) may not show up on a bone scan (FIG 2).

**Laboratory Studies**

- A complete blood count and blood chemistries should be ordered. The calcium level is of specific concern in those studies, because hypercalcemia may be a life-threatening complication of MBD. An ionized calcium level is helpful in the diagnosis of hypercalcemia, because low albumin levels may lower total calcium levels. Hypercalcemia should be treated before any surgical intervention is undertaken. Levels of specific tumor markers should be evaluated, if applicable to the specific tumor type.

**Biopsy**

- The mere presence of a bone lesion with a presumed diagnosis of metastasis does not mandate a biopsy. Such a lesion in a
patient with an established history of malignancy and with radiologic evidence of other bone metastases does not require a biopsy prior to surgical intervention.

- On the other hand, biopsy must be performed on a solitary bone metastasis in a patient with a known history of malignancy or a lesion with atypical radiologic or clinical manifestations, even in the presence of other bone metastases prior to any intervention.

**PREOPERATIVE PLANNING AND CONCERNS**

- Although planned surgery for patients with MBD should not be delayed, preoperative evaluation and staging must not be compromised but, rather, thoroughly mapped out. This evaluation makes it possible to understand the morphology of the lesion and its relation to adjacent structures, determine the

**FIG 2**

- **A.** Plain radiograph showing a pathological fracture of the proximal femur in a 59-year-old woman with multiple myeloma. **B.** Bone scintigraphy revealed no additional bone lesion, and she was treated with open reduction (without tumor removal) and uncemented internal fixation. She reported unrelenting ipsilateral knee pain and was clinically diagnosed as having degenerative joint disease and associated pain. Two weeks after the reduction surgery, she reported an acute onset of severe knee pain and swelling on weight bearing. **C,D.** A pathological fracture of the distal femur was demonstrated on plain radiographs. **E.** This patient underwent total femur resection with endoprosthetic reconstruction.
overall skeletal staging of the patient, and detect any other metastases that may require simultaneous surgery. Because most patients who present with skeletal metastases have an established diagnosis of cancer, clinical and radiologic evaluations usually are aimed at evaluating the extent of the disease and the presence of any complications rather than at identifying its site of origin.

History and Physical Examination

- Medical history should include current oncologic status and related treatments and medications. It is crucial to question the patient or family members about his or her overall functional status and, specifically, about the status of the affected extremity prior to the occurrence of the metastatic lesion. For example, a surgeon would be justifiably reluctant to perform major surgery on a lower extremity in a patient who was bedridden or wheelchair-bound, because stabilization of the extremity for greater ease in maintaining pain-free personal hygiene in that patient would require a less extensive procedure.

- The orthopaedic surgeon also should inform the medical oncologist of the impending operation, verify the oncologic information he or she has received, and be provided with the patient’s estimated life expectancy. The physical examination should include evaluation of the principal symptomatic area as well as other symptomatic sites. Examination should focus on the degree of soft tissue tumor extension and its relation to the neurovascular bundle of the extremity, muscle strength and range-of-motion of the adjacent joints, neurovascular status of the affected extremity, and limb edema.

Impending Pathologic Fractures

- Patients with MBD who have a pathological fracture experience a sudden onset of debilitating pain and loss of function. They require urgent hospitalization, which may interrupt the course of ongoing oncologic treatment. Furthermore, surgery for these fractures often is complicated by the presence of a substantial hematoma, soft tissue edema, and difficulties in obtaining appropriate reduction and alignment because of extensive bone destruction. For these reasons, it is important to identify those metastatic bone lesions that are likely to cause a pathological fracture (ie, “impending” pathological fractures) and to stabilize them prophylactically.

- Although the consensus is that impending fractures require prophylactic fixation, numerous reports have described varying concepts and methods of evaluation of these lesions as well as criteria for defining them. The agreed-to and most commonly used criteria include a lytic bone lesion that measures 2.5 cm, causes circumferential destruction of 50% or more of the adjacent cortical bone, and is associated with increasing pain on weight bearing that has not responded to treatment with radiation therapy (FIG 3).6,7,12

PRINCIPLES OF SURGERY

- The primary goals of surgery for MBD are to achieve local tumor control and structural stability of the surgically treated site. Surgery has no effect on the overall progression of disease or on patient survival. Most failures of these surgeries are attributed to inadequate tumor removal and improper reconstruction. Radiation therapy is most effective when applied to
FIG 4 • (continued)
microscopic disease and is considerably less effective when applied to large tumor volume.

- Surgeries done for impending or current pathological fractures should, therefore, follow the same steps: first, removal of the tumor, and only then reconstruction (FIG 4A–C). The decision to perform intralesional tumor removal or proceed with a resection of the affected bone segment depends on the local extent of bone loss and proximity to the adjacent joint (FIG 4D–K).

- Because bone metastases usually have less soft tissue extension than do primary sarcomas of bone, resection of bone metastases usually does not require en bloc removal of the surrounding soft tissues (FIG 5A,B).

- Reconstruction must provide immediate stability that must not rely on biologic healing processes. Therefore, the use of autologous bone grafts, allografts, or allograft-prosthetic composites is inappropriate in surgery for MBD. Similarly, cementless prosthetic implants have no place in this setting.

- Reconstruction should include the combined use of hardware or prosthetic implants and bone cement (ie, polymethylmethacrylate). The latter is used to reinforce the hardware by increasing the diameter of the construct through which the mechanical load is transmitted and improving its attachment to the neighboring bone, thereby allowing the construct to withstand the mechanical stresses of immediate weight bearing and function.

- Stiffness and strength are related to the diameter of the intramedullary construct: the amount of stiffness in the act of bending is proportional to the diameter raised to the fourth power, and the strength in bending varies with the third power of the diameter (FIG 5C–H).

### POSTOPERATIVE CARE

#### Rehabilitation

- Full weight bearing and passive and active range-of-motion exercises of the adjacent joints should be practiced as soon as possible, depending on wound healing and patient ability.

#### Adjuvant Radiation Therapy

- Postoperative external-beam radiation therapy of 3000 to 3500 Gy routinely is administered to the entire surgical field to control remaining microscopic disease. That dose of radiation does not impede callus formation if it is feasible, as determined by underlying fracture characteristics and the patient’s overall status. Radiation treatment is given to patients once the surgical wound has healed, usually 3 to 4 weeks after surgery.
Primary bone sarcomas usually have considerable extension into the soft tissues. Resection of such tumors at the proximal humerus would require en bloc removal of the overlying deltoid muscle, the rotator cuff tendons, and the joint capsule. Bone metastases, however, usually present with less extensive soft tissue involvement, and their resection involves removal of bony elements with only a thin layer of surrounding soft tissues. A metastatic bone lesion treated by closed nailing. This procedure is simple to perform, but it may fail, because tumor progression leaves the nail as the only load-transmitting component of the lower extremity, ultimately resulting in hardware failure and breakage. D. Plain radiograph showing an impending fracture of the femoral diaphysis due to multiple myeloma. Tumor removal, cemented nailing, and postoperative radiation most likely would have resulted in local tumor control and durable reconstruction. E. Closed nailing was done in this patient, however, and tumor progression (despite radiation) resulted in unavoidable hardware breakage. F. Similar outcome with uncemented fixation of metastatic renal cell carcinoma of the subtrochanteric region. G. Surgery should include meticulous tumor removal and filling of the entire tumor cavity with bone cement. H. Plain radiograph showing renal cell carcinoma (RCC) metastasis to the proximal femur treated with partial removal and cemented intramedullary fixation. RCCs usually are unresponsive to radiation therapy; the remaining tumor in this patient progressed and resulted in hardware failure at the hardware–cement interface.
PEARLS AND PITFALLS

Preoperative
- Acquisition of data regarding patient’s functional status pre-MBD
- Consultation with patient’s medical oncologist for current oncologic status and estimated survival
- General assessment; rule out hypercalcemia
- Plain radiographs of the entire affected bone
- Total body bone scan before surgical intervention
- Evidence of painful lytic long bone metastasis more than 2.5 cm in diameter, occupying over 50% of the cortical diameter, defines an impending fracture that requires prophylactic surgical intervention.

Intraoperative
- Tumor resection is done first
- Reconstruction should include cemented internal fixation—biologic reconstruction is inappropriate

Postoperative
- Immediate weight bearing and range-of-motion exercises
- External-beam radiation therapy

REFERENCES
Cryoablation

A number of mechanisms have been found to be responsible for the tissue necrosis induced by cryoablation. These mechanisms can be grouped into two categories: immediate and delayed.

- Four mechanisms are involved in the immediate cytotoxicity produced by cryoablation: (1) formation of ice crystals and membrane disruption; (2) thermal shock; (3) dehydration and toxic effects of electrolyte changes; and (4) denaturation of cellular proteins. The formation of intracellular ice crystals is considered as being the main mechanism of immediate cellular necrosis.

- The two mechanisms most likely responsible for the delayed, progressive necrosis that is observed following cryoablation and for the problems associated with subsequent repair of frozen tissue are (1) the damage to the microvascular circulation and (2) vascular stasis.

During cryoablation, ice crystals first occur in the extracellular spaces. The withdrawal of water from the system into these crystals creates a hyperosmotic extracellular environment, which, in turn, draws water from the cells. As the process continues, these crystals grow, the cells shrink and dehydrate, electrolyte concentration is increased, and membranes and cell constituents are damaged. Because rapid freezing, such as that achieved by direct pour of liquid nitrogen, does not allow sufficient time for the withdrawal of water from the cells, intracellular ice crystals are formed simultaneously.

Conversely, a slow thaw will cause intracellular recrystallization of the already formed crystals and membrane disruption, whereas a rapid thaw will not.

Repeated freeze–thaw cycles also increase the extent of tissue necrosis because of the improved cold conductivity following the first cycle. Therefore, repeated cycles of rapid freezing and spontaneous thaw achieve the maximal effect of cell necrosis.

Histologically, the most dramatic effect of cryoablation is on the appearance of the bone marrow: a rim of 1 to 2 cm of severe, delayed, progressive necrosis that is observed following cryoablation and for the problems associated with subsequent repair of frozen tissue are (1) the damage to the microvascular circulation and (2) vascular stasis. Because rapid freezing, such as that achieved by direct pour of liquid nitrogen, does not allow sufficient time for the withdrawal of water from the cells, intracellular ice crystals are formed simultaneously.

Conversely, a slow thaw will cause intracellular recrystallization of the already formed crystals and membrane disruption, whereas a rapid thaw will not.

Repeated freeze–thaw cycles also increase the extent of tissue necrosis because of the improved cold conductivity following the first cycle. Therefore, repeated cycles of rapid freezing and spontaneous thaw achieve the maximal effect of cell necrosis.

Histologically, the most dramatic effect of cryoablation is on the appearance of the bone marrow: a rim of 1 to 2 cm of extensive necrosis with minimal inflammatory response appears following direct pour of liquid nitrogen. This is followed by liquefaction and progressive fibrosis. Large, thickened, and thrombosed vessels occasionally are seen as well.

INDICATIONS

Histologic Diagnoses
- Benign–aggressive bone tumors
  - Giant cell tumor
  - Aneurysmal bone cyst
  - Simple bone cyst
  - Fibrous dysplasia
  - Enchondroma
  - Chondroblastoma
  - Eosinophilic granuloma
Osteoblastoma
Chondromyxoid fibroma
Low-grade sarcomas of bone
Low-grade chondrosarcoma
Metastatic tumors

**Morphologic Criteria**
Cryoablation is appropriate for periarticular and sacral lesions in which the circumferential rim of the cortex that remains after tumor removal can hold liquid material and is adequate to ensure a mechanically stable reconstruction.

**SURGICAL MANAGEMENT**
Cryosurgical ablation is carried out in five stages: (1) tumor exposure; (2) thorough curettage; (3) high-speed burr drilling of the tumor cavity; (4) cryoablation; and (5) mechanical reconstruction.5,6,27

**DIRECT POUR LIQUID NITROGEN**
When technically possible, a pneumatic tourniquet is used during the procedure to decrease local bleeding and prevent blood from acting as a heat sink and posing a thermal barrier to cryoablation.
A large cortical window the size of the longest longitudinal dimension of the tumor is made after exposure of the involved bone. It must be elliptical, with its axis parallel to the long axis of bone, to reduce the stress rising effect (TECH FIG 1A–C).

All gross tumor material is removed with hand curettes (TECH FIG 1D–E). This is followed by high-speed burr drilling of all remaining macroscopic disease and the walls of the tumor cavity (TECH FIG 1F).
Bony perforations are identified and sealed with Gelfoam (Upjohn, Kalamazoo, MI) before introduction of the liquid nitrogen. The neurovascular bundle and fasciocutaneous flaps are protected by mobilization and by shielding (with surgical pads) from direct contact with the liquid nitrogen, after which cryoablation is performed.

**TECHNIQUES**

**TECH FIG 1**
A. Plain radiograph showing aneurysmal bone cyst of the proximal humerus. B. The tumor site is widely exposed by a deltopectoral incision, and fasciocutaneous flaps are mobilized to expose the entire extent of the tumor. C. A large cortical window the size of the longest longitudinal dimension of the tumor is made. D. Plain radiograph showing giant cell tumor of the distal femur. E. The tumor is first removed with hand curettes. This should be meticulously performed, leaving only residual microscopic disease in the tumor cavity. (continued)
Curettage is followed by high-speed burr drilling.

The traditional technique of cryoablation entails direct pour of liquid nitrogen through a stainless steel funnel into the tumor cavity, taking care to fill the entire cavity (TECH FIG 2). Thermocouples are used to monitor the freeze within the cavity, cavity wall, adjacent soft tissues, and an area 1 to 2 mm from the periphery of the cavity. The surrounding soft tissues are irrigated continuously with warm saline solution to decrease the possibility of thermal injury.

Freezing (boiling of liquid nitrogen) lasts 1 to 2 minutes and is proportional to the volume of poured liquid nitrogen. It is followed by spontaneous thaw, which occurs over 3 to 5 minutes. The cycle is considered complete once the temperature of the cavity rises above 0°C. The cavity is irrigated with saline after two freeze–thaw cycles have been carried out. At this point, the process of reconstructing the tumor cavity begins.

Reconstruction includes the use of internal fixation and the use of polymethylmethacrylate (PMMA; TECH FIG 3). Subchondral surfaces are reinforced with autologous bone graft before cementation.

CLOSED CRYOABLATION WITH ARGON GAS

Cryoablation using direct pour of liquid nitrogen has several technical drawbacks. First, after it has been poured, there is no control of the overall freezing time or of the temperature at different sites within the tumor cavity. Second, it is a gravity-dependent procedure, ie, the poured liquid cannot reach corners of the tumor cavity that are positioned above the fluid level.

In response to these problems, closed cryoablation using argon gas was developed and became available in the late 1990s. This approach entails filling the tumor cavity with a gel medium, inserting metal probes into the gel, and executing computer-controlled delivery of argon gas through the metal probes.

Argon gas serves as the freezing agent, and the surrounding gel acts as a conducting medium, which distributes the low temperature equally throughout the tumor cavity (TECH FIGS 4, 5, and 6).

Computer-controlled delivery of argon gas allows determination of both the desired temperature throughout the tumor cavity and the overall freezing time, and the use of a viscous gel enables filling of any shape of tumor cavity, regardless of gravity considerations (TECH FIG 7).
Reconstruction includes cemented hardware and reinforcement of subchondral surfaces with autologous bone graft. This principle of reconstruction is applied in all anatomic locations: proximal femur (A), distal femur (B), proximal tibia (C), distal tibia (D), distal radius (E), and proximal ulna (F).

D. The tumor cavity is filled with gel. E. Cryoablation.

TECH FIG 7 • Cryoablation of the proximal ulna (A) and the fourth toe (B) using the closed, argon-based system. It would have been difficult to freeze these sites with direct pour of liquid nitrogen due to the relatively large size of the funnels.

PEARLS AND PITFALLS

Surgery
- Mobilization of the neurovascular bundle and surrounding soft tissues
- Adequately large cortical window
- Meticulous curettage followed by high-speed burr
- Soft tissue protection and warming throughout cryoablation
- Reconstruction of the tumor cavity with cemented hardware and of the subchondral surface with autologous bone graft

Postoperative
- Protected weight bearing postoperatively

POSTOPERATIVE CARE
- Routine perioperative prophylactic antibiotics are administered for 3 to 5 days. Patients with lesions of the lower extremities are kept non-weight bearing for 6 weeks. Plain radiographs are then obtained to rule out fracture and establish bone graft incorporation. Gradual weight bearing is allowed if healing has progressed satisfactorily.

OUTCOMES
- By far the most extensive experience with cryoablation has involved giant cell tumor of bone, a benign-aggressive primary bone tumor. Two thirds of these lesions occur in the third or fourth decades of life, and, in most cases, they are located in the metaphyseal-epiphyseal region of long bones around the articular cartilage. Because wide excision of such tumors would cause major loss of function due to their proximity to the joint, it had been common practice to opt for intralesional procedures, but the rate of local recurrence, mainly after curettage, was unacceptably high (ie, 40%-55%).
- The use of cryoablation with liquid nitrogen, as an adjuvant to curettage and high-speed burr drilling, substantially lowered the recurrence rate. Malawer et al reported a 2.3% recurrence rate among 86 patients treated primarily with cryoablation. They reported good-to-excellent functional outcome in 92% percent of the patients. Because cryoablation provides a nonselective mechanism for cell destruction, it is not surprising that similar rates of local tumor control and associated good
functions were reported with other benign–aggressive and malignant tumors.\(^3,4,9,14,23–25,28,30,31,34,35,37,38,40,44–46,49\)

**COMPLICATIONS**

- Gage et al\(^13\) observed that cryoablation is a double-edged sword, ie, that it induces tumor necrosis with similar injury to the surrounding normal tissues. This potential drawback initially was underestimated by surgeons who pioneered the application of this technique in clinical practice. Inadequate protection of soft tissues, lack of mechanical fixation, and failure to use perioperative antibiotics resulted in unacceptably high rates of fractures, soft tissue injury, infections, and neurapraxias.\(^32\)

- Those complications gave cryoablation its bad reputation and motivated surgeons to refine the surgical technique to include concomitant soft tissue mobilization and protection, stable reconstruction with cemented internal fixation devices, and the use of perioperative antibiotics. As a result, the same authors reported a later series of patients with a significantly reduced rate of those complications.\(^39,52\)

- Postoperative fractures have been a devastating complication of cryoablation (FIG 2A,B). They were considered pathological because they occurred through a mechanically weakened bone and following a minor trauma.\(^4,20,27,33,39\) These fractures healed slowly (over a period of 3 to 9 months) and were associated with a significant loss of function. Lack of stable fixation and early weight bearing were shown to be the important factors leading to these fractures, and the treatment protocol was changed accordingly: the consensus was that cryoablation must be followed by stable reconstruction that includes internal fixation reinforced with PMMA and a strict rehabilitation protocol of gradual weight bearing.\(^27,32,39\) This regimen resulted in a minimal rate of postoperative fractures, as reported in series published from the 1990s to date.\(^4,24,27,44,46,49,50\)

- When such postoperative fractures do occur, surgical intervention usually is not required. The fracture lines invariably are along the internal fixation device, so the fracture is not significantly displaced, and immobilization and avoidance of weight bearing usually are sufficient for treatment. Infections and flap necrosis also have become rare complications due to mobilization and protection of soft tissues prior to freezing and the use of perioperative antibiotics.

- Mobilization of the neurovascular bundle and surrounding soft tissues away from the tumor site, as well as the use of perioperative antibiotics, has led to low rates of infections, thermal injuries, and nerve palsies (FIG 2C). When the latter do occur, the neurologic damage usually is transient and heals spontaneously. Cryoablation also was shown to be associated with minimal damage to the adjacent articular cartilage, with degenerative changes reported in less than 3% of cases in a large series of patients.\(^29\)

---

**FIG 1** • Full flexion of the knee in a 54-year-old man 3 months following cryoablation of a chondrosarcoma of the lateral femoral condyle. It would have been difficult to achieve such a range and muscle strength after the resection of the distal femur that otherwise would have been offered to this patient.

**FIG 2** • A. Plain radiograph showing pathological fracture of the proximal tibia following cryoablation and on weight bearing. Reconstruction following cryoablation in that patient consisted of autologous bone graft only. B. The wide collapse and destruction of the articular surface made resection of the proximal tibia and reconstruction with endoprosthesis inevitable. C. Thermal injury to the leg due to spillage of liquid nitrogen. The soft tissues apparently were not well protected in this patient during freezing. This complication is rare when adequate padding and warming with saline are carried out. It is even more uncommon when using the closed argon-based system, which does not involve any poured fluid whatsoever.
Cryoaclination achieves best local tumor control when applied for microscopic disease and in tumors that have not caused major cortical destruction and invasion into the surrounding soft tissues. Any compromise of either of these criteria ultimately may result in local tumor recurrence. Better case selection, adequate curettage, and meticulous burr-drilling have led to a drop in local recurrence rates, to less than 5% in most series. A second cryoablative procedure is curative in most local recurrences. Venous gas embolism is a rare complication of open cryoaclination with liquid nitrogen, having been reported in only 4 cases. Liquid nitrogen rapidly produces nitrogen bubbles at room temperature. Although most of the gas exits into the atmosphere through the surgical wound, a considerable amount nevertheless is pushed into the pulmonary circulation under the influence of the pressure caused by boiling of liquid nitrogen in the bony cavity, and exhaled. It usually manifests intraoperatively with decreased O2 saturation level and end-tidal CO2, associated with a drop in blood pressure and a rise in the heart rate. These emboli usually resolve completely with early detection, discontinuation of nitrous oxide administration, and support with oxygen.

REFERENCES

BACKGROUND

- The upper extremity is involved by bone and soft tissue neoplasms only one third as often as the lower extremity. The scapula and proximal humerus are common sites of primary sarcoma, including osteosarcoma and Ewing sarcoma in children and chondrosarcoma in adults. Metastatic tumors, especially hypernephroma, also have a propensity for the proximal humerus. When soft tissue tumors occur in the upper extremity, they tend to favor the shoulder girdle and may secondarily involve the scapula, proximal humerus, or clavicle. The axilla is another site around the shoulder girdle where primary soft tissue tumors may develop or where metastases can spread to and replace the local lymph nodes. The axilla is a relatively “silent” area, where tumors may grow to large sizes before they become symptomatic and are detected.

- The shoulder girdle consists of the proximal humerus, the scapula, and the distal third of the clavicle, as well as the surrounding soft tissues. Each bone may be involved by a primary malignant bone tumor or metastases, with or without soft tissue extension. The bones of the shoulder girdle also may be secondarily involved by a soft tissue sarcoma, which requires resection and reconstruction techniques similar to those of a primary bone tumor (FIG 1).

- Until the mid-20th century, forequarter amputation was the treatment for malignant tumors of the shoulder girdle. Today, about 95% of patients with sarcomas of the shoulder girdle can be treated safely by limb-sparing resection such as the Tikhoff–Linberg resection and its modifications. The relation of the neurovascular bundle to the tumor and other structures of the shoulder girdle is the most significant anatomic factor in determining resectability, removal of the tumor, and reconstruction.

- The resection and reconstruction of tumors of the shoulder girdle consists of three components: (1) surgical resection of the tumor following oncologic principles; (2) reconstruction of the skeletal defect (ie, endoprosthetic replacement); and (3) soft tissue reconstruction using multiple muscle transfers to cover the skeletal reconstruction and provide a functional extremity. The goals of all shoulder girdle reconstructions are to provide a stable shoulder and to preserve normal elbow and hand function. The extent of tumor resection and remaining motor groups available for reconstruction dictate the degree of shoulder motion and function that are retained.

Historical Background

- Some of the earliest discussions concerning limb-sparing surgery focused on techniques for resection of tumors about the scapula. Initial reports of shoulder girdle resections were confined to the individual bones or portions of the scapula. The first reported scapular resection was a partial scapulectomy performed by Liston in 1819 for an ossified aneurysmal tumor. Between this time and the mid-1960s, several other authors discussed limb-sparing resections about the shoulder girdle. In 1965, Papioannou and Francis reported 26 scapulectomies and discussed the indications and limitations of the procedure.

- The Tikhoff–Linberg interscapulothoracic resection or triple-bone resection was described in the Russian literature by Baumann in 1914. He referred to a 1908 report by Pranishkov that described the removal of the scapula, the head of the humerus, the outer one third of the clavicle, and the surrounding soft tissue for a sarcoma of the scapula. The shoulder was suspended from the remaining clavicle by metal sutures. Tikhoff and Baumann performed three such operations between 1908 and 1913, and Tikhoff was named as the originator of the procedure. The technique became established in the Western surgical community only after Linberg’s English publication in 1926.

- Classically, most shoulder girdle resections were done for low-grade tumors of the scapula and periscapular soft tissue sarcomas. Before 1970, most patients with high-grade spindle cell sarcomas (eg, osteosarcoma, chondrosarcoma) involving the shoulder girdle were treated with a forequarter amputation. In 1977, Marcove et al were the first to report limb-sparing surgery for high-grade sarcomas arising from the proximal humerus. These authors reported performing an en bloc extra-articular resection that included the proximal humerus, glenoid, overlying rotator cuff, lateral two thirds of the clavicle, deltoid, coracobrachialis, and proximal biceps. Local tumor control and survival rates were similar to those achieved with a forequarter amputation. Resection, however, preserved a functional hand and elbow. These early results were confirmed by other surgeons. After the 1980s, osteosarcoma, chondrosarcoma, and Ewing sarcoma of the proximal humerus became the tumors most commonly treated with a Tikhoff–Linberg resection. A variety of new techniques and modifications of shoulder girdle resections have been developed. Most have been reported as “Tikhoff–Linberg” or “modified Tikhoff–Linberg” resections. These eponyms are not accurate descriptions, however, because the Tikhoff–Linberg procedure was not intended to refer to sarcomas of the humerus.

- As the popularity of limb-sparing surgery for shoulder girdle sarcomas grew, the extent of resection necessary for various tumors, particularly indications for an extra-articular resection, remained a matter of debate. The best method for reconstruction also came under considerable discussion. In response, Malawer et al. developed a surgical classification system (FIG 2) based on tumor location, extent, grade, and pathologic type. This system was intended to provide guidelines regarding the extent of resection necessary for primary bone sarcomas and soft tissue sarcomas that secondarily involve the bones of the shoulder girdle.

SURGICAL CLASSIFICATION SYSTEM

- The current surgical classification system was described by Malawer and associates in 1991 (Fig 2). It is based on the
indications are described briefly in the following section. The current concepts of surgical margins, the relation of the tumor to anatomic compartments (ie, intracompartamental vs. extracompartamental), the status of the glenohumeral joint, the magnitude of the individual surgical procedure, and precise considerations of the functionally important soft tissue components. It includes six categories:

- Type I: intra-articular proximal humeral resection
- Type II: partial scapular resection
- Type III: intra-articular total scapulectomy
- Type IV: extra-articular total scapulectomy and humeral head resection (classic Tikhoff–Linberg resection)
- Type V: extra-articular humeral and glenoid resection
- Type VI: extra-articular humeral and total scapular resection.

Each type is subdivided according to the status of the abductor mechanism (the deltoid muscle and rotator cuff):

- Abductors intact
- Abductors partially or completely resected

Type A resections, in which the abductors are preserved, usually are recommended for high-grade spindle cell bone sarcomas that are entirely intracompartamental (ie, contained within either the proximal humerus or scapula bone). This is a rare situation, however. This type of resection also is recommended for low grade-bone sarcomas, selected metastatic carcinomas, and, often, round cell sarcomas.

Type B resections, in which the abductors are resected, are extracompartamental resections and are the most common type of resection performed for high-grade spindle cell sarcomas.

All six of these types of shoulder girdle resections and their indications are described briefly in the following section. The surgical techniques for each resection and reconstruction are described in ON-8, 10, and 11–13.

GUIDELINES FOR SHOULDER GIRDLE RESECTION

Local Growth and Transarticular Involvement by Shoulder Girdle Tumors

- The shoulder joint appears to be more prone than other joints to intra-articular or pericapsular (ligamentous) involvement by high-grade bone sarcomas.
- Four basic mechanisms underlie tumor spread across the shoulder joint: direct capsular extension; tumor extension along the long head of the biceps tendon; fracture hematoma from a pathologic fracture; and poorly planned biopsy (FIG 3).
- These mechanisms place patients undergoing intra-articular resections for high-grade sarcomas at greater risk for local recurrence than those undergoing extra-articular resections. Therefore, it often is necessary to perform an extra-articular resection for high-grade bone sarcomas of the proximal humerus or scapula.
- Most tumors arise from the metaphyseal portion of the proximal humerus. They extend beyond the cortices and spread underneath the deltoid muscle, subscapularis muscle, and remaining rotator cuff muscles. As the tumor grows, the extrasosseous component spreads along the long head of the biceps tendon, along the glenohumeral ligaments, and underneath the rotator cuff, heading toward the glenoid or directly crossing the glenohumeral joint. The deltoid, subscapularis muscle, and remaining rotator cuff muscles are compressed into a pseudocapsular layer. These muscles form compartmental boundaries around the tumor. The axillary nerve and circumflex vessels enter this compartment. The major neurovascular bundle is displaced by the tumor; however, in most instances the fascia overlying the subscapularis muscle as well as the axillary sheath that contains the blood vessels and nerves protect the major neurovascular bundle from tumor involvement or encasement.
- Similarly, most scapular sarcomas originate from the metaphyseal portion of the scapula or the scapula neck, and grow centripetally into the soft tissues. They form a soft tissue mass that extends outward and usually is contained by the subscapularis and other rotator cuff muscles. These tumors follow the path of least resistance and are directed toward the glenohumeral joint and proximal humerus. Eventually, the tumor contaminates these structures. The subscapularis muscle and its investing fascia function as a barrier and protect the axillary vessels and brachial plexus from tumor invasion. These neurovascular structures usually are displaced by the adjacent tumor that lies deep to the subscapularis muscle.

Functional Anatomic Compartment of the Shoulder Girdle

- Sarcomas grow locally in a centripetal manner and compress surrounding tissues (muscles) into a pseudocapsular layer. The pseudocapsular layer contains microscopic finger-like projections of tumor, which are referred to as satellite nodules.
- Sarcomas spread locally along the path of least resistance. Surrounding fascial layers resist tumor penetration and,
therefore, provide boundaries to local sarcoma growth. These boundaries form a compartment around the tumor (FIG 4).

- A sarcoma will grow to fill the compartment in which it arises, and only rarely will an extremely large sarcoma extend beyond its compartmental borders. In discussing bony sarcomas that extend beyond the cortices into the surrounding soft tissues, the term functional anatomic compartment refers to the investing muscles that are compressed into a pseudocapsular layer (Fig 4).

- These muscles provide the fascial borders of the compartment, a fact that has important surgical implications. A wide resection of a bone sarcoma removes the entire tumor and pseudocapsular layer and must, therefore, encompass the investing muscle layers (compartmental resection).

- The functional compartment surrounding the proximal humerus consists of the deltoid, subscapularis and remaining rotator cuff, latissimus dorsi (more distally), brachialis, and portions of the triceps muscles. The glenoid and scapular neck also reside within the functional compartment of the proximal humerus, because they are contained by the rotator cuff and capsule and the subscapularis muscle. Sarcomas that arise from the proximal humerus and extend beyond the cortices compress these muscles into a pseudocapsular layer.

- The fascial layers surrounding these muscles resist tumor penetration. The only neurovascular structures that enter this compartment are the axillary nerve and humeral circumflex vessels.

- The main neurovascular bundle (i.e., brachial plexus and axillary vessels) to the upper extremity passes anterior to the subscapularis and latissimus dorsi muscles. These muscles and their
investing fascial layers are particularly important, therefore, for protecting the neurovascular bundle from tumor involvement. They also protect the pectoralis major muscle, which must be preserved during surgical resection for soft tissue coverage.

- High-grade sarcomas that extend beyond the bony cortices of the proximal humerus expand the investing muscles that form the compartmental borders and pseudocapsular layer.
- These sarcomas grow along the path of least resistance and, therefore, are directed toward the glenoid and scapular neck by the rotator cuff and glenohumeral joint capsule.
- Anteriorly, the tumor is covered by the subscapularis, which bulges into and displaces the neurovascular bundle. Only rarely does a very large proximal humerus sarcoma extend beyond the compartmental borders.
- In these instances the tumor usually protrudes through the rotator interval. A wide (compartmental) resection for a high-grade sarcoma must, therefore, include the surrounding muscles that form the pseudocapsular layer (ie, deltoid, lateral portions of the rotator cuff), the axillary nerve, humeral circumflex vessels, and the glenoid (extra-articular resection of the proximal humerus).
- Most high-grade scapular sarcomas arise from the region of the scapular neck. The compartmental borders surrounding the scapular neck consist of the rotator cuff muscles and portions of the teres major and latissimus dorsi muscles. The compartment consists of all of the muscles that originate on the anterior and posterior surfaces of the scapula: the subscapularis, infraspinatus, and teres muscles. The deltoid, although it is not typically considered one of the compartmental borders, since it attaches to a narrow region of the scapular spine and acromion, may be involved secondarily by a large soft tissue extension. In most instances the deltoid is protected by the rotator cuff muscles because the anatomic origin of most tumors is from the neck and body region. Similar to the proximal humerus, the rotator cuff muscles are compressed into a pseudocapsular layer by sarcomas that arise from the scapula. The subscapularis also protects the neurovascular bundle from tumor involvement. The head of the proximal humerus is contained within the compartment surrounding the scapula by the rotator cuff muscles. Wide resection of a high-grade scapular sarcoma must, therefore, include the rotator cuff and, in most instances, the humeral head.
- The axillary nerve is not contained within the compartment and therefore can be spared from resection. Additionally, because the deltoid is not compressed into a pseudocapsular layer, it usually can be preserved.

**INDICATIONS**

**Indications for Limb-Sparing Surgery**

- High-grade and some low-grade bone sarcomas
- Soft tissue sarcomas arising from the shoulder girdle

**FIG 3** Biopsy site. Anatomic drawing illustrating the preference for a core needle biopsy for tumors of the proximal humerus. The biopsy sample should be taken through the anterior third of the deltoid. Great care should be taken to avoid the pectoralis major muscle, the deltopectoral interval, and the axillary vessels. The deltoid is innervated by the axillary nerve posteriorly, so a portion of the anterior deltoid can be resected if necessary without significant compromise to the nerve. (Courtesy of Martin M. Malawer. From Bickels J, Jellinek S, Shmookler BM, et al. Biopsy of musculoskeletal tumors. Current concepts. Clin Orthop Relat Res 1999;368:212–219.)

**FIG 4** Schematic diagram of the compartment of the proximal humerus. A true compartmental site includes the muscles of origin and insertion of a specific group, as well as a major feeding vessel and nerve. This is a conceptual consideration for tumors around the proximal humerus, which does not fit the classic definition of an anatomic compartment. Surgically, however, this area is considered as the shoulder girdle compartment, which consists of the deltoid, the rotator cuff muscles, a portion of the pectoralis major muscle, the latissimus dorsi, and the teres major. The major neurovascular pedicle is the axillary nerve and the circumflex vessels. (Courtesy of Martin M. Malawer. From Wittig JC, Bickels J, Kellar-Graney KL, et al. Osteosarcoma of the proximal humerus: long-term results with limb-sparing surgery. Clin Orthop Relat Res 2002;(397):156–76.)
- Metastatic carcinomas: isolated metastasis or metastatic lesions that have caused significant bony destruction
- Occasionally, benign-aggressive tumors also may require these treatment techniques.
- Selection of patients for limb-sparing surgery is based on the anatomic location of the tumor and a thorough understanding of the natural history of sarcomas and other malignancies.

**Contraindications for Limb-Sparing Surgery**

- Absolute contraindications for limb-sparing procedures include tumor involvement of the neurovascular bundle, or a patient’s inability or unwillingness to tolerate a limb-sparing operation.
- Relative contraindications may include chest wall extension, pathologic fracture, previous infection, lymph node involvement, or a complicated, inappropriately placed biopsy that has resulted in extensive hematoma, which has resulted in tissue contamination.

**Biopsy Site**

- One of the most common causes for forequarter amputation is an inappropriately placed biopsy site that has resulted in contamination of the pectoralis muscles, neurovascular structures, and chest wall. Extreme care must be taken with biopsy placement and technique (see Fig 3).

**Vascular Involvement**

- Fortunately, most tumors of the proximal humerus are separated from the anterior vessels by the subscapularis, latissimus dorsi, and coracobrachialis muscles. It is rare for the axillary or brachial artery to be involved with tumor, although a large soft tissue component may cause displacement and compression.
- In general, if the vessels appear to be involved with tumor, the adjacent brachial plexus also is involved, and a limb-sparing procedure may be contraindicated.

**Nerve Involvement**

- The three major cords of the brachial plexus follow the artery and vein and rarely are involved with tumor. The axillary nerve may be involved by neoplasm as it passes from anterior to posterior along the inferior glenohumeral joint capsule. Resection of the axillary nerve usually is required for stage IIB tumors of the proximal humerus.
- The musculocutaneous and radial nerves rarely are involved. The deficit created by resecting the radial nerve is greater than that for the musculocutaneous nerve, but this should not be an indication for amputation.
- If resection will lead to a major functional loss and a close margin (increasing the risk of local recurrence), amputation should be considered. Direct tumor extension into or encasement of the brachial plexus necessitates a forequarter amputation.

**Lymph Nodes**

- Bone sarcomas rarely involve adjacent lymph nodes; nevertheless, axillary nodes should be evaluated and may require biopsy. In the rare incidence of lymph node involvement documented by biopsy, a forequarter amputation may be the best method for removing all gross disease.
- Alternatively, a lymph node dissection in conjunction with a limb-sparing procedure may be considered. Malawer has found, based on two cases, that local control and long-term survival can be obtained by this method (unpublished data).

**Chest Wall Involvement**

- Tumors of the shoulder girdle with large extraosseous components occasionally may involve the chest wall, ribs, and intercostal muscles.
- Chest wall involvement should be evaluated preoperatively with physical examination and imaging studies; however, such involvement often is not determined until the time of surgery. It is not an absolute indication for forequarter amputation; a limb-sparing procedure combined with a chest wall resection may be performed, depending on the involvement of adjacent soft tissues and neurovascular structures.

**Previous Resection**

- The local recurrence rate is increased in cases in which a wide resection is attempted (1) following a previous inadequate resection around the shoulder girdle or (2) when a tumor already has recurred locally. This possibility must be a consideration especially with tumors of the scapula and clavicle and of soft tissue tumors that involve the proximal humerus.

**Infection**

- In patients with high-grade sarcomas, limb-sparing procedures performed in an area of infection are extremely risky, because these patients must receive postoperative adjuvant chemotherapy. If an infection cannot be eradicated with the primary resection, amputation is advisable.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

**Physical Examination**

- The physical examination is important for assessing tumor resectability and for estimating the extent of resection that may be required. Physical examination is important in determining tumor extension into the glenohumeral joint, neurovascular involvement, or tumor invasion of the chest wall. If tumor has invaded the joint, shoulder range of motion usually is reduced, and the patient may complain about discomfort and pain.
- Neurovascular involvement or compression may be suggested by an abnormal neurovascular examination or by decreased or absent pulses.
- Tumors that move freely with respect to the chest wall usually are separated from it by at least a thin tissue plane through which it is safe to dissect.

**Determining Tumor Resectability**

- High-grade tumors arising from the shoulder girdle region often are large and encroach on the neurovascular bundle. Tumors that encase or invade the brachial plexus are considered unresectable. In many cases it is difficult to determine, both clinically and radiologically, which tumors involve or encase the neurovascular structures directly as opposed to merely displacing these structures. Although most tumors that displace the neurovascular structures are resectable, some are unresectable, and it can be difficult to determine clinically which are in this category.
We have found the clinical triad of intractable pain, motor deficit, and a venogram showing obliteration of the axillary vein to be very reliable in predicting brachial plexus invasion. No single imaging study is available that accurately visualizes the brachial plexus. MRI and CT scans typically show a large tumor juxtaposed to the neurovascular bundle (FIG 5).

Venography, however, is extremely accurate in predicting brachial plexus invasion. The axillary vein, axillary artery, and brachial plexus travel in intimate association within a single fascial sheath, the axillary sheath. The major nerves and cords travel along the periphery of the sheath; therefore only complete obliteration—not just compression—of the brachial or axillary vein denotes direct tumor extension in and around the nerves and also indicates secondary involvement of the venous wall. This progression also explains the clinical triad of pain, motor loss, and venous obstruction. Tumors that invade or encase the brachial plexus obliterate the axillary vein because of that vein’s thin walls and low intraluminal pressure. In these instances arteriography demonstrates displacement of the axillary artery; however, the axillary artery remains patent because of its thick walls and high intraluminal pressures.

The final decision regarding the need for a forequarter amputation should be reserved until surgical exploration of the brachial plexus has been performed.

**Prosthetic Reconstruction**

When endoprosthetic reconstruction was developed in the 1940s, attention initially was focused on reconstruction of skeletal defects of the lower extremity. Use of the technique was broadened gradually to include defects of the upper extremity and shoulder girdle. The MRS shoulder prosthesis has undergone several design changes and improvements since that time. The current components for proximal humerus and scapular replacement are shown in Chapters ON-10 and 8, respectively. The MRS is used in conjunction with both intra- and extra-articular resections, and results are highly predictable and successful.

Reported rates of fracture, infection, nonunion, reoperation, and tumor recurrence are lower, and length of immobilization is shorter with extremity endoprosthetic reconstruction than with allograft, composite reconstruction, or arthrodesis.

Survival of the MRS proximal humeral prosthesis is reported to be 95% to 100% at 10 years.

**FIG 5** • Imaging studies of the shoulder girdle and axillary space demonstrating bony and soft tissue findings. A. CT scan showing a tumor arising from the glenoid and involving the glenohumeral joint. CT scans are the best modality for observing bony detail. B. Coronal MRI scan showing direct tumor extension. C,D. A large soft tissue axillary tumor protruding anteriorly through the pectoralis major and the skin. This is a high-grade fungating soft tissue sarcoma. MRI is the best scan for evaluation of soft tissue masses in relation to other soft tissue structures. E. MRI scan of the axillary space (coronal view) showing a secondary skipped lesion along the axillary vein, coming from a high-grade soft tissue sarcoma lower in the axilla. Metastatic lesions of the axilla and lymph nodes are a common source of large axillary masses and are best evaluated by MRI scans. F. Angiography and embolization of metastatic renal cell carcinoma (hypernephroma) to the distal clavicle. Following embolization, there is no evidence of a tumor blush. Embolization often is performed for large high-grade soft tissue sarcomas prior to a resection. G. On this axillary venogram, the axillary vein is occluded by thrombosis, and there is a small backward filling from the innominate vein. This is the most pathognomonic finding of brachial plexus involvement seen during the time of surgery. Brachial plexus involvement often correlates with the clinical findings of neurologic deficits, numbness, or muscle weakness of the affected extremity.
SKELETAL RECONSTRUCTION FOLLOWING HUMERUS AND SCAPULA RESECTIONS

- Special prosthetic replacements are recommended for skeletal reconstruction following proximal humerus and total scapula resections, although the utilitarian approach may be used with any method of reconstruction (TECH FIG 1).
- Soft tissue reconstruction is accomplished using a dual suspension technique that employs static and dynamic methods of prosthetic stabilization and soft tissue and motor reconstruction.
- Static methods of stabilization include the use of heavy nonabsorbable sutures, Dacron tapes, or Gore-Tex grafts, depending on the site of tumor resection and the prosthesis that is being used. This method offers secure fixation and stabilization of the prosthesis until the soft tissues heal and scar to each other.
- Dynamic methods of stabilization and reconstruction include multiple muscle rotation flaps and muscle transfers that eventually heal, scar to each other and the prosthesis, and provide the necessary motor units for a functional extremity.
- Soft tissue reconstruction follows skeletal reconstruction and static stabilization. The short head of the biceps is attached with a tenodesis proximally to the coracoid (intra-articular proximal humerus reconstruction), or to the clavicle (extra-articular proximal humerus reconstruction) or pectoralis major (total scapula reconstruction). The pectoralis minor also is tenodesed back to its origin, when possible, or to the scapula to protect the neurovascular structures. The pectoralis major is repaired to its humeral insertion or, in cases requiring extra-articular proximal humerus reconstruction, transferred to cover the prosthesis with soft tissues. The latissimus dorsi may be transferred laterally to function as an external rotator following extra-articular proximal humerus resection.
- In total scapula reconstruction, the periscapular muscles are tenodesed to the prosthesis with heavy nonabsorbable sutures or tapes in a manner that covers the entire prosthesis with muscle. Following isolated axillary tumor resection, the distal (humeral) transected edge of the latissimus dorsi muscle is rotated into the defect and sutured to the superficial surface of the subscapularis muscle to fill the dead space. Large-bore closed suction drains are routinely placed prior to skin closure.
The initial steps of the anterior approach of the utilitarian shoulder girdle incision. The key to this approach is the release of the pectoralis major from its insertion on the humerus (1–2 cm away). With the pectoralis major now reflected onto the chest wall, the entire axillary space can be exposed. This is termed the first layer of musculature of the axillary space. The second muscular layer of the axillary space is then visualized. With the pectoralis major layer retracted, the axillary space is completely covered by fascia, similar to the peritoneum. This covers two muscles, the short head of the biceps and the pectoralis minor, which attach to the coracoid process, which must be released. With these two muscles released, the axillary space and infra-clavicular component of the brachial plexus (ie, the axillary vein and artery through its entire length) can be explored completely. If necessary, a portion of the clavicle can be resected to exposed the subclavian artery and vein. (Courtesy of Martin M. Malawer.)

PEARLS AND PITFALLS

Preoperative evaluation
- Physical examination and radiologic imaging modalities are useful for predicting whether a tumor is resectable. The scapula and proximal humerus should move freely from the chest wall. Chronic swelling in the distal extremity, intractable pain, motor loss, and a venogram that demonstrates obliteration of the axillary vein strongly suggest that the tumor is unresectable. The final determination regarding the need for a forequarter amputation is made intraoperatively, after anterior exposure and exploration of the brachial plexus and neurovascular structures.

Neurovascular exploration and mobilization
- The key to a safe and adequate resection of all types of neoplasms around the shoulder girdle lies in adequate visualization, exposure, dissection, mobilization and preservation of all vital neurovascular structures. Full exposure is facilitated by releasing the pectoralis major muscle from its humeral insertion and the strap muscles from the coracoid process.

Type of resection
- High-grade sarcomas that arise from the proximal humerus or scapula are likely to contaminate or cross the glenohumeral joint, either grossly or microscopically. An extra-articular type of resection is used for most high-grade sarcomas arising from the scapula or proximal humerus. Clavicular tumors, although less common, require a slightly different surgical approach (FIG 6).

Soft tissue reconstruction
- Soft tissue reconstruction is just as important as skeletal reconstruction during limb-sparing surgery if a functional extremity is to be provided. Static and dynamic methods of soft tissue reconstruction and stabilization are used. Static methods rely on heavy nonabsorbable sutures, Dacron tapes, and Gore-Tex grafts. Dynamic methods rely on multiple muscle transfers and rotational muscle flaps.
OUTCOMES

- The types of tumors, anatomic locations, and types of shoulder girdle resections performed in 143 patients treated at the authors’ institutions from 1980 to 1998 are shown in FIGURE 7A. Experience in these patients with endoprosthetic reconstruction of the proximal humerus and scapula demonstrates that this is a reliable and durable technique of reconstruction (FIG 7B–E). Survival rates based on Kaplan–Meier analysis demonstrate a 9-year survival rate of 98% to 99% for proximal humeral replacements.
- No mechanical failures or dislocations occurred. Other groups have reported a significant incidence of dislocation following endoprosthetic reconstruction of the shoulder girdle, but this has not been our experience.
- The results shown in Figure 7 reflect the use of “dual suspension” (ie, both static and dynamic) or capsular reconstruction techniques and meticulous attention to soft tissue reconstruction.

FIG 6 • Example of a safe exposure of a clavicular tumor. The tumor arising from the distal clavicle is a solitary metastasis. The trapezius has been mobilized. The pectoralis major has been detached from the clavicle, and the deltoid has been detached from the acromion.

REFERENCES

BACKGROUND

- Tumors arising from the scapula may become very large before diagnosis. Initially, they are often contained by muscle, which protects other tissues within the shoulder girdle. Patients with scapular tumors often present with pain, a mass, or both.
- Chondrosarcomas are the most common primary malignancy of the scapula in adults; in children the most common primary malignancy of the scapula is the round cell tumor Ewing sarcoma.
- Soft tissue tumors may involve the periscapular musculature and secondarily invade the scapula.
- The majority of shoulder girdle malignancies can be treated safely with limb-sparing surgeries in lieu of forequarter amputation. Indications for limb-sparing surgeries at this location include most high-grade bone sarcomas and some soft tissue sarcomas, depending on the tumor extension.
- Scapular tumors, like tumors of the proximal humerus, require careful preoperative staging, appropriate imaging studies, and a thorough knowledge of local anatomy. Selection of patients whose tumor does not involve the neurovascular bundle, thoracic outlet, or adjacent chest wall is required.
- It is rare when forequarter amputation is indicated. It is mainly reserved for patients with large, fungating tumors or infected tumors; those in whom limb-sparing resection has failed; and those with tumors invading the major nerves and vessels or the chest wall.
- Before 1970, most patients with high-grade sarcomas arising from the scapula were treated with a forequarter amputation. The first limb-sparing surgeries for high-grade sarcomas arising from the shoulder girdle were reported by Marcove et al in 1977. They reported that the Tikhoff-Linberg resection (FIG 1A) achieved local tumor control and survival similar to that achieved with a forequarter amputation. Most importantly, a functional hand and elbow were preserved. Limb-sparing surgery for patients with high-grade sarcomas in this location soon became standard treatment. Today, the majority of malignancies arising from or involving the scapula can be treated safely with limb-sparing surgery in lieu of a forequarter amputation.
- Shoulder motion and strength are nearly normal after a partial scapular resection (type II). However, there is significant loss of shoulder motion, predominantly shoulder abduction, after a total scapular resection (type III), alone or in conjunction with an extra-articular resection of the shoulder joint and proximal humerus (types IV and VI). Suspension of the proximal humerus and meticulous soft tissue reconstruction are the keys to providing shoulder stability and a functional extremity. If significant periscapular muscles remain after tumor resection (especially the trapezius and deltoid muscles), a total shoulder–scapula prosthesis may be the optimal reconstructive option (FIG 1B–F).

ANATOMY

- The local anatomy of a scapular tumor determines the type of scapular resection and subsequent reconstruction. Because these tumors become quite large before diagnosis, the surgeon should thoroughly inspect the chest wall, axillary vessels, proximal humerus and rotator cuff, and periscapular tissue to ensure that an appropriate procedure is planned.
- Sarcomas involving the glenoid, scapular neck, or supraspinatus musculature usually involve the glenohumeral joint and adjacent capsule. Therefore, an extra-articular resection through a combined anterior and posterior approach should be performed for tumors in this location.
- Large sarcomas of the scapula with soft tissue extension can involve the axillary vessels and the brachial plexus. Likewise, lymph nodes in the surrounding region should be evaluated to determine resectability.
- Suprascapular tumors are difficult to palpate on physical examination. Even sophisticated imaging modalities may incorrectly estimate the extent of these tumors. Tumors in this location can extend into the anterior and posterior triangles of the neck, making resection impossible except in the cases of palliation.

Key Anatomic Structures of the Scapular Region

Neurovascular Bundle

- The subclavian artery and vein join the cords of the brachial plexus as they pass underneath the clavicle. Beyond this point the nerves and vessels are surrounded by a fibrous sheath and can be considered one structure (ie, the neurovascular bundle).
- The suprascapular, dorsal scapular, and circumflex scapular vessels form an extensive vascular network around the posterior scapula. Each of these vessels must be ligated and transected to resect the scapula.

Axillary Vessels

- The axillary blood vessels are a continuation of the subclavian vessels as they pass underneath the clavicle and are called the brachial vessels once they pass the inferior border of the latissimus dorsi muscle. The axillary vessels pass medial and inferior to the coracoid process en route to the proximal humerus. They are surrounded by the brachial plexus throughout their entire course.
- The artery yields several branches during its course. The first branch arises as the artery passes over the first rib and is called the supreme thoracic artery. While the artery is deep to the pectoralis minor muscle, the thoracoacromial artery arises followed by the lateral thoracic artery and then the subscapular artery. The thoracoacromial artery gives rise to four branches, one of which supplies the area around the acromion.
- The subscapular artery divides into the thoracodorsal artery and the circumflex scapular artery that wraps around the lateral border of the scapula and tethers the axillary vessels to the scapula.
The anterior and posterior humeral circumflex arteries are the final branches of the axillary artery. They arise at the level of the inferior border of the subscapularis muscle and wrap circumferentially around the humeral neck. The axillary nerve runs with the posterior humeral circumflex vessels. The humeral circumflex vessels tether the neurovascular structures down to the proximal humerus and hence to any neoplasm that arises from this site. Early ligation of the circumflex vessels is a key maneuver in resection of scapular sarcomas because it permits mobilization of the axillary and brachial vessels and brachial plexus away from the tumor mass. The humeral head articulated with a polyethylene glenoid but was held in place only by muscle transfers and/or the use of a Gore-Tex sleeve. The second-generation of the scapula that was used in the late 1990s. This prosthesis offered fenestrations within the body of the scapula to allow the adjacent muscles to tenodese to give the recreated shoulder a new and more stable attachment. The proximal humeral component could, at this point, be mated with the Modular Replacement System for resections of the proximal humerus. This greatly increased the surgeon’s ability to reconstruct the proximal humerus and shoulder girdle. The third-generation scapular prosthesis that was developed by Howmedica, Inc. (now Stryker Orthopedics, Mahwah, NJ). This prosthesis is the first articulating scapular prosthesis. The bipolar proximal humeral head fits into the glenoid with a polyethylene retaining rim. Gross specimen after an extended Tikhoff-Linberg resection (type IV) that included the entire scapula, an extra-articular resection of the glenohumeral joint, and a portion of the proximal humerus with all of the muscles attached.

The suprascapular nerve arises from the superior trunk of the brachial plexus as it passes over the first rib. It travels posterior through the scapular notch deep to the transverse scapular ligament and supplies the supraspinatus and infraspinatus muscles.

Musculocutaneous and Axillary Nerves

These two nerves are often in close proximity to or in contact with tumors around the scapula. The musculocutaneous nerve is the first nerve to arise from the brachial plexus. It arises from the lateral cord just distal to the coracoid process, passes through the coracobrachialis, and runs between the brachialis and biceps. It should be preserved, if possible, to maintain elbow flexion.

The path of this nerve may vary extensively. It usually passes 2 to 7 cm inferior to the coracoid process. Tumors that arise from the scapula often displace this nerve anteriorly so that it occupies a position only 1 to 2 mm deep to the fascia. Care should be taken when opening the fascia overlying this nerve in the interval between the coracobrachialis and pectoralis minor muscles. The nerve should be identified and protected before releasing any muscles from the coracoid process because it can be easily injured during the resection.

The axillary nerve arises from the posterior cord of the brachial plexus and courses, along with the posterior humeral circumflex vessels, inferior to the distal border of the sub-
scapularis. It then passes between the teres major and minor muscles to innervate the deltoid muscle posteriorly. Tumors of the scapula usually displace and stretch the axillary nerve. The nerve is usually protected from the tumor by the subscapularis muscle.

**Radial Nerve**
- The radial nerve arises from the posterior cord of the brachial plexus. It passes anterior to the latissimus dorsi—teres major insertion on the humerus. Just distal to the latissimus dorsi insertion, the nerve courses into the posterior aspect of the arm, just lateral to the long head of the triceps, to run in the spiral groove between the medial and lateral heads of the triceps. The radial nerve must be isolated and protected before resection.

**Upper and Lower Subscapular Nerves and Thoracodorsal Nerve**
- The upper and lower subscapular nerves and the thoracodorsal nerve arise from the posterior cord of the brachial plexus near where the subscapular artery and humeral circumflex vessels arise from the axillary artery. The upper and lower subscapular nerves descend and enter directly into the substance of the subscapularis muscle. These nerves are routinely ligated during a scapulectomy. The thoracodorsal nerve passes with the thoracodorsal artery distally, directly anterior to the subscapularis muscle, to supply the latissimus dorsi muscle. The thoracodorsal nerve can usually be spared during most scapular resections.

**INDICATIONS**
- Limb-sparing surgery is indicated for most sarcomas of the scapula (FIG 2).

**Contraindications for Limb-Sparing Surgery for Scapula Tumors**
- Tumor invasion or encasement of the brachial plexus and axillary vessels. Involvement of a single nerve is not an absolute contraindication.
- Extensive chest wall involvement
- Relative contraindications include:
  - An inappropriately placed biopsy that has resulted in extensive contamination of the surrounding soft tissues
  - An active or previous infection

**FIG 2** • Indications for scapulectomy. **A.** MRI (T2-weighted signal) shows an extensive tumor arising from the coracoid and involving the scapula and the glenohumeral joint. **B.** Bone scan of a large giant cell tumor of the scapula with complete scapula involvement. This study revealed that there was minimal bone remaining. **C.** An extremely large periscapular soft tissue sarcoma arising adjacent to the scapula and scapular musculature and also involving the musculature of the proximal humerus. The initial procedures performed by Tikhoff and Linberg (reported in 1928) were resections for periscapular soft tissue sarcomas and not primary or metastatic bony sarcomas. **D.** Angiography of an osteosarcoma of the scapula before induction chemotherapy. There is marked vascularity and displacement of the axillary artery as well as the circumflex vessels.
A recurrent sarcoma that cannot be adequately resected without performing a forequarter amputation

Presence of a displaced pathological fracture secondary to a sarcoma, which does not heal after preoperative chemotherapy

**IMAGING AND OTHER STAGING STUDIES**

**Plain Radiography**
- Plain radiography is often the first imaging modality in the diagnosis of tumors of the scapula. This will reveal most bony and some soft tissue involvement. The scapula can sometimes be difficult to visualize on plain radiographs because it is often obscured by the rib cage. Mineralization shown on plain radiographs may help categorize a bone sarcoma as either an osteosarcoma or chondrosarcoma.

**Computed Tomography and Magnetic Resonance Imaging**
- CT and MRI are the most valuable means of determining the size and extent of extraosseous disease and its relationship to the axillary vessels, glenohumeral joint, and chest wall (see Fig 1C–E).
- CT is extremely important for evaluating the rib cage. Subtle erosion of the rib cage by an adjacent scapula tumor is better visualized on a CT scan than an MRI. It is the best test for detecting subtle mineralization within tumors as well as for detecting subtle areas of scapular involvement by adjacent soft tissue sarcomas. Contrast-enhanced CT is particularly helpful for determining the proximity of the tumor to the axillary and brachial vessels and brachial plexus.
- MRI is most accurate for determining intraosseous and extraosseous tumor extent as well as for detecting skip metastases. An appreciation of the intraosseous extent is necessary for determining the length of bone resection. The proximal humerus is usually transected approximately 2 to 3 cm distal to the intramedullary extent of the neoplasm as visualized on a T1-weighted MRI image. The proximity of the extraosseous component to the axillary and brachial vessels and brachial plexus can also be evaluated.

**Bone Scan**
- A bone scan is helpful in identifying bony involvement of the proximal humerus or ribs in the regional area, and metastatic disease in the entire bony skeleton. Since the scapula is very thin throughout the major part of its body, the bone scan may not be as accurate as when evaluating the long bones for tumor extent.
- The bone scan should be correlated with an MRI.
- It is also used to detect bony metastases.
- The bone scan can also be beneficial when evaluating the chest wall and proximal humerus for local extension.

**Angiography and Other Studies**
- Angiography can determine vascular involvement and reveal any anomalies of the vascular anatomy. Displacement of the axillary vessels is indicative of anterior tumor extension into the axilla.
- Axillary venography is performed if there is any clinical suspicion of brachial plexus involvement, such as nerve pain or distal edema, the hallmarks of invasion of the brachial plexus. Occluded axillary veins seen on venography correlate with brachial plexus infiltration.

**Biopsy**
- We recommend fine-needle or core biopsies be performed under CT or fluoroscopic guidance in an attempt to protect the neurovascular bundle.
- One puncture site is required. The needle is then reintroduced through that site at various angles to obtain cores from several different regions of the tumor.
- The biopsy site should be placed along the intended incision site of the resection (FIG 3).
- A posterior needle biopsy is recommended for tumors arising within the body of the scapula; the anterior approach should be avoided to minimize the risk of soft tissue contamination by tumor.

**Scapular Biopsies**
- Biopsies of the scapular body are more difficult to perform than biopsies of the proximal humerus. They should be performed along the lateral or axillary aspect of the scapula and not along the vertebral (medial) border or directly posterior through any potential skin flaps.
- The biopsy site should be along the intended incision site of the resection. A posterior needle biopsy is recommended for tumors arising within the body of the scapula; the anterior approach should be avoided.
Biopsies of tumors in the lateral aspect of the scapula or glenoid region should be performed along the lateral or axillary aspect of the posterior scapula directly through the infraspinatus or teres minor muscles.

SURGICAL MANAGEMENT

Preoperative Planning

- All imaging studies, particularly CT, MRI, angiography or venography, are reviewed before surgery to determine surgical resection type and feasibility.
- The patient is examined for distal edema and motor loss, which may indicate brachial plexus infiltration, an unresectable situation. The scapula should also move free from the chest wall, indicating that gross chest wall invasion is unlikely.
- Distal pulses are checked before surgery to ensure adequacy.
- The MRI and CT are reviewed to determine the proximity of the neoplasm to the brachial plexus and axillary vessels as well as to the chest wall. The soft tissue extent of the lesion is determined and a judgment is made about preservation of important periscapular muscles, essential for prosthetic reconstruction of the scapula. The arteriogram and venogram are also reviewed. Final determination of resectability and the use of a total scapula prosthesis, if the tumor is deemed resectable, is made intraoperatively.

Positioning

- The patient is placed in a lateral or semilateral position that permits access to the posterior aspect of the shoulder girdle all the way to the spinous processes. The affected extremity is prepared and draped free (FIG 4A).

Approach

- Most tumors of the scapula or periscapular soft tissues that require a total scapula resection are resected through a combined anterior and posterior approach. Most of these tumors have a large anterior soft tissue component that is juxtaposed to or that displaces the axillary vessels and brachial plexus.
- The anterior approach is crucial in these instances to explore and mobilize these structures away from the neoplasm so that a safe and adequate resection can be performed. The procedure uses both incision A (anterior extended deltopectoral incision) and incision B (posterior incision) of the utilitarian shoulder girdle incision (FIG 4B).
- Occasionally, a total scapula resection can be performed solely through a posterior approach for neoplasms that do not have an anterior soft tissue component. The surgeon must have a thorough knowledge of the course of axillary vessels, brachial plexus, and all of its branches to perform this procedure safely entirely through a posterior approach. If there are any uncertainties, then the procedure is most safely performed through a combined anterior and posterior approach.
- The axillary vessels and plexus are explored and mobilized anteriorly. This requires the pectoralis major to be detached and reflected for adequate exposure.
- The posterior incision permits the release of all muscles attaching to the scapula.
- The glenohumeral joint is removed extra-articularly. The osteotomy is performed below the level of the joint capsule.
- A scapular prosthesis is used if sufficient musculature remains; specifically, the deltoid, trapezius, rhomboids, and latissimus dorsi muscles are required for a prosthetic replacement.
- If there is not sufficient musculature after the resection, the remaining humerus is supported from the clavicle with Dacron tape (static suspension) and the conjoin tendon (dynamic suspension) and a pectoralis major rotational flap is also performed.
A utilitarian incision of the shoulder girdle. Occasionally a scapula resection can be performed completely through the posterior incision; however, if there is a large anterior tumor extension with displacement of the axillary vessels or an extraosseous soft tissue component, it is much safer to proceed with an anterior approach similar to the proximal humeral resections.

**EXTRA-ARTICULAR TOTAL SCAPULA AND HUMERAL HEAD RESECTION (TYPE IV): THE TIKHOFF-LINBERG PROCEDURE**

- This procedure is an extra-articular en bloc resection of the scapula, glenohumeral joint and humeral head, and distal clavicle.
- Incision: A utilitarian anteroposterior approach is used.
- A large posterior fasciocutaneous flap is developed.
- The rhomboids and trapezius muscles are released from the vertebral border of the scapula and the latissimus dorsi muscle is mobilized but not transected.
- If the tumor does not involve the deltoid or the trapezius, the muscles are preserved and are reflected off the scapular spine and acromion. The classic Tikhoff-Linberg resection does not preserve the deltoid or trapezius muscles.
- An osteotomy below the humeral head (i.e., a scapulectomy and extra-articular resection of the glenohumeral joint in conjunction with the scapula) is performed.
- Prosthetic reconstruction: If there are significant remaining muscles after a type IV shoulder girdle resection, then a scapula prosthesis is used (TECH FIG 1A).
- The scapula prosthesis is fenestrated to permit the muscles to tenodese to themselves. It has holes drilled along the axillary and vertebral borders for fixation with Dacron tapes.

- The scapula prosthesis is sutured first to the rhomboid muscles with Dacron tape, and then the latissimus dorsi is rotated over the body of the scapula prosthesis and sutured along the vertebral border.
- The humeral component is then inserted into the osteotomized proximal humerus. A Gore-Tex graft is used to reconstruct the capsular mechanism (TECH FIG 1B).
- The Gore-Tex is sutured to the proximal humerus prosthesis and the glenoid neck on the scapula prosthesis with 3-mm Dacron tape (TECH FIG 1C, D).
- The muscle closure consists of tenodesis of the deltoid to the trapezius and the latissimus over the rhomboids and to the serratus anterior muscles. The scapula prosthesis fits between the serratus anterior and the latissimus dorsi and rhomboid muscles.
- The deltoid and trapezius muscles have been preserved and are tenodesed together. The latissimus dorsi is rotated up to the lower border of the deltoid and to the rhomboid muscles.
- The latissimus is sutured to the holes in the axillary border of the scapula prosthesis and the adjacent musculature using Dacron tape and Ethibond sutures, respectively.
A scapula prosthesis in place with a proximal humeral prosthesis seated. The proximal humeral prosthesis is cemented in place before suturing the scapula to the chest wall. Technique of Gore-Tex capsule reconstruction. Reconstruction of an artificial capsule is essential for appropriate function and stability. Even though the third-generation scapular prosthesis offers a “snap-fit,” it can dislocate due to the continuous traction forces caused by the weight of the arm. Muscle reconstruction is completed by rotating the latissimus dorsi over to the rhomboids and the trapezius to the deltoid. All of these muscles are then tenodesed to themselves.

**TECH FIG 1 • A–D.**

**INTRA-ARTICULAR SCAPULAR RESECTION (TYPE III)**

- This resection is an intra-articular total scapulectomy. It is most commonly performed for soft tissue sarcomas that secondarily invade the scapula.
- A posterior and anterior incision is used, respectively.
- The posterior deltidoid is released from the acromion and scapular spine. The trapezius muscle is released and retracted.
- The rhomboid muscles are released starting at the inferior angle of the scapula.
- The tip is then elevated and the scapula is retracted away from the chest wall as muscle release continues medially, laterally, and then superiorly to permit visualization of the axilla and chest wall.
- The inferior tip of the scapula is rotated, and traction is applied with the arm abducted. The axillary contents are gently retracted.
- The neurovascular structures are approached from the back, unless the tumor has an anterior extraosseous component.
- The neurovascular structures are visualized as the scapula is retracted away from the chest wall.
- The infraspinatus and supraspinatus muscles are transected and the joint is entered.
- The anterior capsule and the subscapularis tendon are transected.
- The long head of the biceps is identified, tagged with suture, and divided.
- The acromioclavicular joint is entered and released or the distal portion of the clavicle is resected with the specimen.
- As the scapula is gently elevated, the short head of the biceps and the coracobrachialis and pectoralis minor muscles are released from the coracoid.
- The musculocutaneous nerve must be protected as it passes near the coracoid.
- The dual suspension technique using Dacron tape to suspend the proximal humerus from the clavicle can be used.
- Dacron tape (3-mm) is used to suspend the remaining humerus from the distal clavicle. The biceps, coracobrachialis, and triceps are reattached through drill holes in the distal clavicle.
- If the deltidoid muscle has been preserved, it is tenodesed anteriorly to the pectoralis major and trapezius muscles to further reconstruct the anterior aspect of the shoulder girdle.
- If adequate musculature remains, a total scapular prosthesis (see Tikhoff-Linberg Techniques) can be used to reconstruct the defect (TECH FIG 2).
- There are two major pairs of muscles that must be reconstructed: the trapezius muscle to the remaining portion of the deltidoid (this is tenodesed over the superior third of the prosthesis and glenohumeral joint) and then the rhomboid muscles to the prosthesis (covered by the transfer of the latissimus dorsi from its origin). This forms a nice pocket for the prosthesis to sit in between the latissimus dorsi and rhomboids and against the serratus anterior and chest wall.
**TECH FIG 2** • **A.** A scapula prosthesis in place with a proximal humeral prosthesis seated. The proximal humeral prosthesis is cemented in place before suturing the scapula to the chest wall. This allows for correct positioning and retroversion of the humeral component. **B.** Muscle reconstruction.

**PEARLS AND PITFALLS**

**Preoperative evaluation**
- MRI and CT are important for evaluating the proximity of the tumor to the neurovascular structures, chest wall invasion, and involvement of other key muscles around the scapula.

**Resection**
- Most total scapula resections (extra-articular and intra-articular) are performed through an anterior and posterior approach. This is the safest method when a large anterior soft tissue component exists.

**Exposure of neurovascular structures**
- The axillary vessels and brachial plexus are best exposed through an anterior approach (extended deltopectoral incision) that involves releasing the pectoralis major muscle from its humeral insertion and the coracobrachialis muscle and the short head of biceps and pectoralis minor muscle from their coracoid attachments.

**Posterior exposure and exploration**
- During the posterior portion of the resection it is important to preserve the periscapular muscles, which are crucial for prosthetic reconstruction, if possible. These muscles include the rhomboids, trapezius, deltoid, serratus anterior, and latissimus dorsi muscles. The axillary nerve must also be preserved.

**Prosthetic reconstruction**
- A small scapular component is used if it will facilitate better soft tissue coverage. The humeral component is chosen to allow for up to 2 cm of shortening of the extremity, which also facilitates soft tissue closure. A constrained total scapula is preferred. A Gore-Tex aortic graft is used to reconstruct the glenohumeral joint capsule. The scapula prosthesis is positioned as medial as possible (1 to 2 cm away from the spine) in a pocket between the rhomboids and serratus anterior muscles. The deltoid and trapezius muscles are retensioned as they are sutured to each other and to the prosthesis. The latissimus provides final coverage of the prosthesis. At the conclusion of the procedure, the entire prosthesis must be thoroughly covered with muscle.

**Postoperative care**
- The patient is kept in a brace for 6 weeks with the arm abducted 45 to 60 degrees and the elbow flexed 45 degrees.
POSTOPERATIVE CARE

- Epineural catheters are routinely used with a continuous bupivacaine (4 to 8 mL of 0.25% bupivacaine) infusion for 3 to 5 days.
- A special brace is recommended for 6 weeks postoperatively that will hold the arm in 45 to 60 degrees of abduction and the elbow flexed 45 degrees.
- Postoperatively, a sling is required for 4 to 6 weeks.
- In the immediate postoperative period the patient is instructed on motion exercises for the wrist and hand, and elbow flexion is encouraged within the confines of the sling.
- Neck motion and shoulder elevation exercises are instituted within 1 to 2 days after surgery.
- Once the incision has healed and the sutures are removed, at 2 to 4 weeks after surgery, pendulum exercises and gentle shoulder motion (flexion, extension, internal and external rotation) are done with the help of a family member or physical therapist.
- Elbow flexion, extension, supination, and pronation are also performed.
- Gentle strengthening is instituted once motion has returned, with the use of active motion and isometric exercises and light weights (2 to 10 pounds). At 12 weeks postoperatively, strengthening is initiated with Thera-Bands and other resistance exercises up to a 10-pound weight limit. Ultimately the patient is restricted to a 15- to 20-pound weight limit.
- Long-term weightlifting restrictions of less than 20 pounds are generally recommended.

OUTCOMES

- Prosthetic reconstruction of the scapula is a very reliable method of reconstruction after an intra-articular or extra-articular resection of the scapula.
- All patients have a painless, stable shoulder girdle and functional use of the hand and elbow. Rotation below the shoulder is preserved and ranges from –10 degrees of external rotation to T6 for internal rotation. Internal rotation, adduction, and extension strength are virtually normal.
- Active forward elevation and abduction (combined glenohumeral and scapulothoracic motion) range from 25 to 45 degrees and are grade 3 to 4 in terms of motor strength.
- Scapular protraction, retraction, and elevation are restored. These muscles participate in stabilizing the upper extremity when lifting objects. Patients can lift and carry objects up to 20 pounds. Most patients can perform push-ups. Upper extremity strength is better than when the shoulder is left flail or the remaining humerus is suspended from the clavicle. The Musculoskeletal Tumor Society Score for Upper Extremity Function ranges from 24 to 27 out of 30 points (80% to 90%) (FIG 5).
- Elbow, wrist, and grip strength are normal in all patients.
- All patients can reach the tops of their heads, opposite shoulder and armpit, and perineal area with their hand. There are no limitations in activities of daily living, including feeding, dressing, and personal hygiene. Lifting ability is normal with the arm at the side of the body. Cosmesis is acceptable.
- The major limitations have been with recreational activities and other activities that require the arm to be lifted above the shoulder level.

COMPLICATIONS

- Complications from a prior biopsy with extensive contamination of tissues may make a limb-sparing scapular resection inadvisable; therefore, an appropriately placed and performed biopsy must occur.

FIG 5 • A. Wound closure with good approximation and no tension. The perineural catheter is placed into the brachial plexus sheath before wound closure. This provides excellent postoperative anesthesia with minimal sensory deficit when 0.25% bupivacaine is used. B. Posterior view of a scapular prosthesis 13 years after reconstruction. Quite impressive symmetry has been attained when comparing the operative and contralateral sides. C. Push test, which is designed to test the rhomboids, serratus anterior, and latissimus dorsi. There is minimal winging of the scapula. In addition, the cosmetic effect of retaining the trapezius and the deltoid is impressive and evident. D,E. Patient performing a push-up. Great strength and stability of the shoulder girdle is seen here. This stability permits the patient to place the hand in three dimensions in space, the anatomic function of the normal shoulder girdle. Hand and elbow function is normal after these resections. It is extremely rare to have to resect any chords of the brachial plexus, which would result in loss of function of the distal portion of the arm.
■ If the deltoid muscle cannot be preserved, a scapular prosthesis may not be used.
■ Loss of function of activities above the level of the shoulder girdle should be anticipated: the goal of this surgery is to permit good use of the hand and elbow.
■ Skin necrosis occurs rarely. Dislocation of the reconstructed scapular mechanism is rare. In less than 5% of patients, glenohumeral dissociation occurs; it can usually be treated conservatively.

REFERENCES
Several types of resections are available for tumors of the shoulder girdle. The type of resection has a major influence on the choice of reconstruction. Resections can range from intra-articular resection of the proximal humerus to extra-articular resection of the humerus and scapula. Varying amounts of soft tissue also can be resected.

Functional recovery is related to preservation of the axillary nerve and the shoulder abductors. If the glenoid and abductor mechanism can be preserved, a “functional” arthroplasty can be performed.

Three types of arthroplasty are possible:
- A metallic humeral prosthesis can be implanted. The soft tissues (rotator cuff, capsule, and deltoid) cannot be sewn to the prosthesis effectively; therefore, limited function is achieved.
- The most common arthroplasty is an osteoarticular allograft, in which the upper humerus and joint are replaced with a frozen bone allograft. The soft tissues can be repaired to the graft, allowing significant functional recovery. This reconstruction, however, is associated with joint collapse, fracture, and secondary arthrosis.
- Another alternative is an allograft prosthetic composite. This procedure replaces the removed bone stock with an allograft but combines it with a metallic implant. It allows for soft tissue attachment to the allograft. The rotator cuff, deltoid, and capsule can be sewn to the soft tissues of the humeral allograft to maintain shoulder stability and improve shoulder active range of motion. The metallic device has potential to decrease long-term complications of the osteoarticular allograft.

A “functional” arthroplasty is possible only after an intra-articular resection with abductor preservation (FIG 1). It makes little sense to do an arthroplasty if neither the axillary nerve nor the abductors are available. In that case, other reconstructive options, including arthrodesis to a “spacer” metallic hemiarthroplasty, are more appropriate.

**INDICATIONS**

Intra-articular resection of the upper end of the humerus is indicated for benign but aggressive tumors, such as giant cell tumors or low-grade sarcomas, including chondrosarcoma. It also may be a reasonable choice for a sarcoma that has been pretreated with chemotherapy with a good response, including osteosarcoma, Ewing sarcoma, and malignant fibrous histiocytoma.

Appropriate imaging studies should be performed to ensure that the axillary nerve and abductor muscles, along with the rotator cuff, can be preserved.

If an intra-articular resection can be performed, the two most functional reconstructions to maintain shoulder stability and elevation include an allograft prosthetic composite arthroplasty and an osteoarticular allograft. Allograft prosthetic composite (APC) arthroplasty potentially avoids long-term complications of a frozen osteoarticular allograft, including fracture, joint collapse, and arthritis.

**ANATOMY**

- Tumors of the upper end of the humerus either are contained within the bone or have soft tissue extension. Soft tissue extension can be either very limited or extensive. The critical musculature of the upper end of the humerus includes the deltoid, innervated by the axillary nerve, and the rotator cuff, innervated by the suprascapular nerve (FIG 2).
- Other important muscles that must be detached from the upper humerus include the pectoralis major, latissimus dorsi, and teres major. The biceps and coracobrachialis, along with the musculocutaneous nerve, usually can be preserved by dissection and displacement. In the area of the coracoid, the brachial plexus nerves and the axillary artery and vein that become the brachial artery and vein must be dissected and protected.
- The axillary nerve and posterior humeral circumflex artery that pass through the quadrangular space before innervating the deltoid must be preserved to maintain abductor function. It also is important that the radial nerve be protected as it passes behind the humerus distal to the deltoid insertion. The subscapularis is detached away from the tumor and the lesser tuberosity. An arthrotomy then is performed to ensure there is no contamination of the shoulder joint by tumor, and then a circumferential arthrotomy is performed so that the upper end of the humerus can be detached once the bone is divided.

**PATIENT HISTORY AND PHYSICAL FINDINGS**

- Patients with a tumor of the upper end of the humerus present with pain, loss of function, and a mass. Restricted range of motion typically occurs. Some patients actually present with neuropathic symptoms, including anesthesia or paresthesia involving nerves around the upper end of the humerus. Pain is the most common complaint. The pain is both activity-related and at night and usually requires analgesia. It is not uncommon for the patient to report some form of work-related or athletic injury at the time of presentation. Symptoms can last anywhere from days to months.
- Examination of the shoulder girdle includes range of motion, palpation, and a careful neurologic examination.
  - Range of motion can vary considerably but usually is diminished, especially abduction and flexion.
  - Palpation of the shoulder girdle and axilla may detect a mass or lymph node enlargement. It is important to note the location of the mass, especially if it extends into the axilla or in other areas of the shoulder girdle.
  - The neurologic examination includes examination of the axillary, radial, median, ulnar, and musculocutaneous nerves. Loss of any function of these nerves is a more ominous physical finding that often precludes an intra-articular resection of the upper humerus.
It also is important to check the circulation of the limb, starting with the axillary vessel, and examining the brachial vessel all the way to palpation of the radial artery, and to perform an Allen test to make sure there is an ulnar artery.

**IMAGING AND OTHER STAGING STUDIES**

**Imaging**

- For tumors of the upper end of the humerus, a series of imaging studies is performed to determine resectability and reconstruction.
- Radiographs, including anterior-posterior, external rotation lateral, and axillary lateral views, (FIG 3A,B), give important clues to the diagnosis. The plain radiograph is the most important initial diagnostic tool in coming up with a differential diagnosis of the type of neoplasm present. Three-dimensional imaging of the upper end of the humerus also is important.
- MRI is very useful for looking at the soft tissue extent of the tumor and its relation to the neurovascular bundle (FIG 3C).

MRI also is very helpful in determining the intramedullary extent of the tumor. This is particularly important for tumors such as chondrosarcoma, where the intramedullary extension goes well beyond the prediction by the plain radiograph.
- CT scans are better for defining bone involvement and may be helpful for some tumors.
- A bone scan is performed to determine whether there are skip lesions or involvement of other bones, suggesting polyostotic disease (FIG 3D). Multicentric osteosarcomas, for instance, are not terribly rare and can be detected by a technetium Tc 99m bone scan.
- Angiograms rarely are needed nowadays because of the availability of sophisticated three-dimensional imaging with infusion, such as MRI.
- If the plain radiograph suggests a sarcoma, then a CT scan of the chest for staging typically is performed before the biopsy so that the area is not distorted by general anesthesia and postanesthesia atelectasis.

**Biopsy**

- The biopsy of tumors of the upper end of the humerus is very important for ultimate resectability. The types of biopsies can be fine needle, for cytology; core needle, for histology; or open incisional.
- Placement of the biopsy is critical (FIG 4). The location usually is determined by the MRI scan and the presence of a soft tissue mass.
- Typically, the soft tissue component of the tumor is biopsied rather than going deep into the bone. The biopsy site should be located so that it can be resected along with the upper end of the humerus when the definitive operation is performed.
- The biopsy site for the soft tissue mass usually is reached by going through muscle. Because most surgical resections of the upper end of the humerus use the deltopectoral groove, this groove should be avoided during the biopsy. The surgeon should, instead, go through muscle, either the deltid or the pectoralis, on one side of the groove or the other.
- An adequate amount of tissue should be biopsied to obtain a correct diagnosis.
- The surgeon consults with the pathologist to determine the appropriate type of biopsy.
For most high-grade bone sarcomas, including osteosarcoma, Ewing sarcoma, and malignant fibrous histiocytoma, neoadjuvant chemotherapy is delivered prior to the primary resection. Neoadjuvant chemotherapy, if effective, causes tumor necrosis and margination. This makes limb salvage surgery, including an intra-articular resection of the humerus, a safer procedure.

**SURGICAL MANAGEMENT**

### Preoperative Planning

- Special equipment is necessary for intra-articular resection of the humerus followed by an allograft prosthetic composite arthroplasty. The most notable is the frozen bone allograft, along with a long-stemmed humeral prosthesis. The surgeon must contact a tissue bank, preferably one accredited by the American Association of Tissue Banks, to ensure that a frozen humerus is available before the procedure.
- The surgeon should receive a radiograph of the allograft for sizing purposes. For an allograft prosthetic composite arthroplasty, the allograft must be long enough to replace the resected bone and of an appropriate size to accept a long-stemmed humeral prosthetic hemiarthroplasty device. A template of that device with a sizing ruler is helpful in choosing the right allograft. The allograft radiograph also should have a sizing device.
- The humeral allograft must have a retained soft tissue cuff for repair. Some humeral allografts come without this cuff; this operation cannot be done with that type of allograft.
- The surgeon also should template the glenoid to ensure that the appropriate metallic hemiarthroplasty is available (FIG 5A). A long-stem metallic device usually is used. Sometimes the long stem, which passes through the allograft and into the host bone, provides for a rigid press fit, and no additional internal fixation is necessary. In other cases, the stem acts only as a partial fixation device that provides bending stability, but an additional dynamic compression or locking plate will be necessary to provide rotational stability at the junction between the allograft and the host bone junction (FIG 5B).

### Positioning

- Positioning of the patient on the operating table must allow for an extensile exposure of the shoulder girdle. A towel roll typically is placed behind the medial border of the scapula so that access to the front and the back of the shoulder is obtained and the scapula and glenoid are stabilized. The limb is then prepped and draped in a free manner so that it can be manipulated during the operative procedure.
Development of the Deltopectoral Groove

- The biopsy site must be excised as the deltopectoral groove is dissected. The cephalic vein is either retracted or suture ligated, and the groove is developed from the clavicle to the deltoid insertion. The dissection can be carried down between the insertions of the deltoid and the pectoralis major.
- The exposure can be extended distal to the lateral aspect of the biceps and brachialis if necessary (TECH FIG 1A).
- The musculocutaneous nerve and the biceps attachment to the coracoid are identified along with the nerves of the brachial plexus and vessels. These structures are dissected and retracted medially.

Soft Tissue Detachment

- The deltoid is detached from the deltoid tuberosity. The pectoralis major, teres major, and lattisimus dorsi muscles are detached from the humeral shaft. The rotator cuff tendons—subscapularis from the lesser tuberosity, and the supraspinatus, infraspinatus, and teres minor tendons from the greater tuberosity—are detached.
- The tendons are tagged with sutures for control and identification.
- The shaft of the humerus is isolated distal to the tumor.

Arthrotomy

- The anterior capsule is divided to determine tumor contamination of the joint. Then a circumferential arthrotomy is done until the humeral head can be dislocated. The inferior capsule must be released from the humeral neck, with the incision continued posteriorly. The axillary nerve can be protected by doing the release with the patient’s arm adducted and progressively rotated externally while incising the capsule off the humerus.

Bone Division

- The humerus is then divided with a power oscillating saw distal to the tumor. The cut must have a significant margin of normal bone and marrow distal to the tumor, as determined by the preoperative MRI scan and measurements.
- Chandler retractors are placed around the bone to ensure protection of the radial nerve (TECH FIG 1B).

Dissection of the Quadrilateral Space

- The axillary nerve and the posterior humeral circumflex vessels are identified in the quadrilateral space and dissected and preserved all the way to the deltoid muscle.

Removal of Specimen and Inspection of Margins

- The humeral specimen is removed after the remaining soft tissue attachments are cut. It usually is divided on the back table with a power oscillating saw, and gross inspection of margins is done (TECH FIG 1C). Microscopic margins also can be sent from the marrow space.

Reconstruction

- The reconstruction is performed with new gowns, gloves, and instruments. Before the resected specimen is removed, it is measured precisely. The allograft that has been procured is thawed in room-temperature lactated Ringer’s solution.

Preparation of the Allograft

- After thawing, the allograft is measured and the soft tissue cuff inspected. The humeral allograft is divided with a power oscillating saw at the appropriate position to replace all resected humerus.
- The articular portion of the humeral allograft is resected at the anatomic neck, from the greater to the lesser tuberosity, with a power saw. The allograft is then prepared on the back table for the metallic humeral device using the system chosen by the surgeon.
- The bone of the upper end of the humerus typically is opened with a high-speed, high-torque burr. The humeral canal is prepared with the appropriate cylindrical reamers. The humeral allograft is then opened with the appropriate-sized rasps or broaches to accept the humeral component.
**Techniques**

- Long-stemmed humeral components are available in 170-mm and 200-mm lengths. Depending on the length of the humeral resection, the humeral component length is chosen to allow the stem to extend at least 2 cortical diameters into the host bone. The diameter of the prosthetic stem is determined by the size of the allograft canal and the size of the host bone canal.
- The long-stemmed humeral device is then inserted through the allograft with the stem extending beyond the end of the allograft to engage the host bone canal. All shoulder prosthetic systems now offer various humeral head sizes, and have eccentric offsets to match anatomy and fine tune stability. A trial humeral head is placed on the stem. A trial seating of the humeral construct into the native canal and into the glenoid is performed to ensure humeral head size, height, and position within the glenoid. This also allows the surgeon to evaluate available rotator cuff length and soft tissue tension for repair around the prosthesis. If anything, a slightly larger humeral head is chosen.

**Preparation of the Host Bone**

- The diaphysis of the humeral host bone is cylindrically reamed to accept the allograft prosthetic composite implant. If a press fit is possible, then line-to-line reaming is performed. If not, the host bone is cylindrically reamed larger than the humeral stem but then will need to be additionally fixed with an internal fixation device.

**Trial Seating of the Device**

- The allograft prosthetic composite implant is inserted into the humeral host bone, and then the shoulder is reduced. The appropriate retroversion of the humeral head is selected.
Retroversion typically is 30 degrees from the epicondylar axis of the elbow to the humeral head. Another way to determine the correct rotation is to have the prosthetic humeral head pointing directly into the glenoid with the forearm in neutral rotation. The chosen retroversion position is marked at the junction between the allograft and the host bone.

Rotation should be evaluated to ensure stability, because retroversion is a variable in the proximal humerus.

**Cementing of the Allograft**

- On the back table the humeral allograft is washed and dried, and cement is mixed. The cement is pressurized into the humeral allograft, and then the metallic prosthesis is inserted cephalad to caudal through the allograft with the stem extending beyond the bone cut. It is important to clean the stem of all cement while it is doughy so that the cement does not interfere with insertion into the humeral host bone.

- The cemented allograft prosthesis composite then is either press fit into the host bone or simply inserted, followed by internal fixation. Obviously, the more proximal the resection, the more native humeral canal is available, and the easier it is to obtain press-fit stability.

- The appropriate rotation for the 30 degrees of humeral retroversion is critical. If adequate rotational stability is not available at the allograft–host bone junction, a lateral dynamic compression plate or locking plate is used, applying the appropriate principles.

- If screws are used, they can be either unicortical or bicortical with compression principles at the allograft–host bone junction. Locking plates also allow for cerclage wire, which can be inserted around the humerus for additional fixation. It is important not to place unfilled screw holes in the allograft, because they act as stress risers and areas of revascularization that could lead to fracture.

**Soft Tissue Repair**

- The allograft prosthetic composite arthroplasty then is reduced into the shoulder joint, and a circumferential repair of soft tissue is performed. Nonabsorbable suture, of at least no. 2 or no. 5, is used for the repair. The capsule is repaired to the capsule of the allograft circumferentially in an interrupted manner.

- The supraspinatus, infraspinatus, and teres minor tendons are reattached to their corresponding tendons with nonabsorbable suture. It is easiest to begin the rotator cuff repair posteriorly and proceed to the supraspinatus and then the subscapularis.

- Subscapularis tendon repair is critical for anterior stability. The native capsule and rotator cuff tendons should be repaired to their corresponding allograft structures. The deltoid is reattached to the deltoid tendon on the allograft, and, if possible, the pectoralis major is reattached to its tendon.

- Using the appropriate tension for this repair is important. Placing the shoulder and arm in the “salute” position and then tying the tendons helps in obtaining the correct tension. Based on the compression obtained at the allograft–host bone junction, the surgeon can elegantly graft this junction with a bone graft substitute or even an autogenous graft (TECH FIG 1D).

**Closure and Immobilization**

- The wound is then closed over drainage tubes in multiple layers, and the shoulder is placed in an abduction shoulder brace, with the shoulder abducted 30 degrees and internally rotated 45 degrees.

---

**PEARLS AND PITFALLS**

---

**COMPLICATIONS**

- The risk of infection is 1% to 2% and the risk of nonunion is 10% to 20%.
- The most common problem is subluxation of the gleno-humeral joint, depending on the amount of soft tissue available for reconstruction.

**POSTOPERATIVE CARE**

- The patient is maintained in an abduction orthosis for the early postoperative period. The Hemovac drain is discontinued, and the patient is discharged.
- Tendon healing and repair is allowed for approximately 4 weeks, after which gentle shoulder exercises are begun. At
first, pendulum exercises of the shoulder are performed, with some gentle passive and passive-assisted exercises to follow.

- Approximately 6 weeks postoperatively, gentle active exercises are initiated, but no resistance is applied to the soft tissue repair for 2 months. At that point, more aggressive range-of-motion and muscle exercises are started to maximize the functional recovery.

- Serial radiographs are performed to check for healing at the allograft–host bone junction. Typically, union at this junction occurs somewhere between 3 months and 12 months postoperatively. If a nonunion develops and 1 year has passed, then autogenous grafting is performed to augment the healing.

OUTCOMES

- Although allograft prosthetic composite arthroplasty is one reconstructive option available for most tumor surgeons, little has been published on this operation.6

- In 2003, Dudkiewicz et al4 reported on 11 patients treated with an allograft prosthetic composite arthroplasty of the upper humerus. All patients were treated for an osteosarcoma, most of which were stage IIB. At the most recent follow-up, 10 of the 11 patients were alive, and they reported good function of the upper extremity. The function was not detailed in terms of range of motion, muscle strength, or joint stability. The authors reported several complications, including nonunion at the allograft–host bone junction and wound infections.

- Jensen and Johnston7 reported on four patients with an allograft prosthetic composite using the Neer prosthesis and found excellent outcomes.

- In 2005, Kassab et al8 reported on three patients with an allograft prosthetic composite of the humerus. The Musculoskeletal Tumor Society (MSTS) functional score for this small series was 76%.

- Damron et al2 functionally evaluated shoulder reconstruction and concluded that the osteoarticular allograft procedure had the best outcomes if the abductors of the shoulder are preserved.

- O’Connor, Sim, and Chao9 reported on one of the largest series of upper humerus reconstructions (57 patients). An osteoarticular allograft, which was used in eight patients, had the best functional outcomes in their cohort. Four of eight of these grafts fractured. Other authors reported outcomes with osteoarticular allograft reconstruction after an intra-articular resection.1,10

- DeGroot et al3 reported a 37% allograft fracture rate and recommended the osteoarticular allograft be filled with cement to decrease this problem. Some of the fractured allografts were salvaged with an allograft prosthetic composite arthroplasty.

- Wang et al11 reported osteoarticular allograft fractures in 14 of their 20 patients.

- In 1999, Getty et al5 reported on 16 patients who had undergone intra-articular resection of the proximal humerus with an osteoarticular allograft reconstruction. The MSTS functional evaluation showed a mean recovery of 70%. Complications reported in this series included four fractures of the allograft and one infection. Survivorship of the frozen allograft at 5 years was 68%. Other complications reported included glenohumeral instability in three patients and dislocation of the glenohumeral joint in eight patients. The authors concluded that an osteoarticular allograft has a high complication rate, and were reluctant to continue to perform this procedure. Whether an allograft prosthetic composite arthroplasty will improve these outcomes remains to be seen.

- At this time, the advantage of allograft prosthetic composite arthroplasty over osteoarticular allograft arthroplasty remains questionable.

REFERENCES

BACKGROUND

- The proximal humerus is a common site for both primary osteosarcomas and chondrosarcomas. Metastatic tumors occasionally involve the shoulder girdle and often are treated using the same resection and reconstruction techniques (FIG 1A).
- Limb-sparing resection of the proximal humerus is challenging. Despite their complexity, these resections can be performed in about 95% of patients with high- or low-grade sarcomas. Amputations rarely are required.
- Endoprosthetic reconstruction is the most common technique for reconstructing large proximal humeral defects. It is used following both intra-articular (type I) and extra-articular (type V) resections. This type of reconstruction is combined with local muscle transfers to create shoulder stability, cover the prosthesis, and provide a functional elbow, wrist, and hand (FIG 1B).
- The surgical and anatomic considerations of limb-sparing procedures of the proximal humerus and the specific surgical techniques for type I and type V resection and reconstruction are described in this chapter. Total humeral replacement is described briefly.
- The proximal humerus is one of the most common sites for high-grade malignant bone tumors in the adult, and it is the third most common site for osteosarcoma.1 Tumors in this location tend to have a significant extrasosseous component. The proximal humerus also may be involved by metastatic cancer (especially renal cell carcinoma) and secondarily by soft tissue sarcomas, which require a resection similar to that used for primary bone sarcomas with extrasosseous extension.
- About 95% of patients with tumors of the shoulder girdle can be treated with limb-sparing resections.
- The Tikhoff–Linberg resection and its modifications are limb-sparing surgical options for bone and soft tissue tumors in and around the proximal humerus and shoulder girdle. Portions of the scapula, clavicle, and proximal humerus are resected in conjunction with all muscles inserting onto and originating from the involved bones. Careful preoperative staging and selection of patients whose tumor does not encase the neurovascular bundle or invade the chest wall are required.
- A classification system for resection of tumors in this location is described in Figure 1B. The most common procedure for high-grade sarcomas of the proximal humerus, type VB, is described.
- We do not recommend type I resection for high-grade tumors, due to the increased risk of local recurrence.
- Optimal function is achieved with muscle transfers and skeletal reconstruction. A prosthesis is used to maintain length and stabilize the shoulder and distal humerus following resection. A stable shoulder with normal function of the elbow, wrist, and hand should be achieved following most shoulder girdle resections and reconstructions performed using the techniques described.

INDICATIONS

- Indications for limb-sparing procedures of the proximal humerus and shoulder girdle include high-grade and some low-grade bone sarcomas, as well as some soft tissue sarcomas that secondarily invade bone.
- Occasionally, solitary metastatic carcinomas to the proximal humerus are best treated by a wide excision (ie, type I resection).
- The decision to proceed with limb-sparing surgery is based on the location of the tumor and a thorough understanding of its natural history. Recently, we have treated patients with pathologic fractures with induction chemotherapy, immobilization, and limb-sparing surgery if there is a good clinical response and fracture healing.
- Absolute contraindications include tumor involvement of the neurovascular bundle or extensive invasion of the adjacent chest wall (FIG 2).
- Relative contraindications include chest wall extension, tumor contamination of the operative site from hematoma following a poorly performed biopsy or pathologic fracture, a previous infection, or lymph node involvement.

UNIQUE ANATOMIC CONSIDERATIONS

- Resection and reconstruction of the proximal humerus and shoulder girdle is a technically demanding procedure.
- The local anatomy of the tumor often determines the extent of the operation required. The surgeon should be experienced with all aspects of shoulder girdle anatomy and the unique considerations it may present.

Proximal Humerus

- Malignant tumors often present with large soft tissue components (stage IIB) underneath the deltoid that extend medially and displace the subscapularis and coracobrachialis muscles.2 Pericapsular and rotator cuff involvement occur early and must be evaluated.

Glenohumeral Joint

- The shoulder joint appears to be more prone to intra-articular or pericapsular involvement by high-grade bone sarcomas than are other joints.
- Four basic mechanisms exist for tumor spread: direct capsular extension; tumor extension along the long head of the biceps tendon; fracture hematoma from a pathologic fracture; and poorly planned biopsy.
- These mechanisms place patients undergoing intra-articular resections for high-grade sarcomas at greater risk for local recurrence than those undergoing extra-articular resections.
FIG 1 • A. Anatomy of the shoulder girdle. B. Surgical classification of shoulder girdle resections. This system was initially proposed by Malawer in 1991. Types I through III are intra-articular resections, whereas types IV through VI are extra-articular.

A, abductor muscles retained; B, abductor muscles resected.

Chapter 10 PROXIMAL HUMERUS RESECTION WITH ENDOPROSTHETIC REPLACEMENT

Musculocutaneous and Axillary Nerves
- The musculocutaneous and axillary nerves often are in close proximity or contact with tumors around the proximal humerus.
- The musculocutaneous nerve is the first nerve that leaves between the teres major and minor to innervate the deltoid muscle posteriorly.
- Tumors of the proximal humerus are likely to involve the axillary nerve as it passes adjacent to the inferior aspect of the humeral neck, just distal to the joint. Therefore, the axillary nerve and deltoid almost always are sacrificed during proximal humerus resections.

Radial Nerve
- The radial nerve comes off the posterior cord of the plexus and continues anterior to the latissimus dorsi and teres major. Just distal to the teres major, the nerve courses into the posterior aspect of the arm to run between the medial and long head of the triceps.
- Although most sarcomas of the proximal humerus do not involve the radial nerve, it must be isolated and protected prior to resection.

Axillary and Brachial Arteries
- The axillary artery is a continuation of the subclavian artery, and is called the brachial artery after it passes the inferior border of the axilla. The axillary vessels are surrounded by the three cords of the brachial plexus and brachial plexus. The axillary artery typically leaves the lateral cord just distal to the coracoid process, passes through the coracobrachialis, and runs between the brachialis and biceps. Preservation of the musculocutaneous nerve and short head of the biceps muscle is important to ensure normal elbow function.
- The path of this nerve may vary extensively (within 6–8 cm of the coracoid) and should be identified before any resection is performed, because the nerve can easily be injured.
- The axillary nerve arises from the posterior cord and courses, along with the circumflex vessels, inferior to the distal border of the subscapularis. It then is tethered to the proximal humerus by the anterior and posterior circumflex vessels. Early ligation of the circumflex vessels is a key maneuver in resection of proximal humeral sarcomas, because it allows the entire axillary artery and vein to fall away from the tumor mass.
- Occasionally, anatomic variability in the location of the branches of the nerve may lead to difficulty in identification and exploration if the variation has not previously been recognized. A preoperative angiogram is helpful in determining vascular displacement and anatomic variability.
- Final determination of tumor resectability is made at surgery. Early exploration of the neurovascular structures is performed following division of the pectoralis major muscle. This approach does not jeopardize subsequent formation of an anterior flap in patients who require forequarter amputation.

IMAGING AND OTHER STAGING STUDIES
- Appropriate imaging studies are key to successful resections of tumors of the proximal humerus and shoulder girdle (Fig 3A–E).

Therefore, it often is necessary to perform an extra-articular resection for high-grade bone sarcomas of the proximal humerus or scapula.

Neurovascular Bundle
- The subclavian artery and vein join the cords of the brachial plexus as they pass underneath the clavicle.
- Beyond this point, the nerves and vessels can be considered as one structure (ie, the neurovascular bundle). Large tumors involving the upper scapula, clavicle, and proximal humerus may displace the infraclavicular components of the plexus and axillary vessels.

Fig 2 • A. Schematic drawing showing a resectable tumor. The tumor is compressing and displacing the neurovascular bundle; however, there is no invasion or encasement. This situation commonly arises in the treatment of a sarcoma. An angiogram or venogram would show patency of the axillary vessels. B. Schematic drawing showing an unresectable tumor. The tumor is infiltrating the neurovascular structures and obliterating the axillary vein. Venography would show a non-patent axillary vein, whereas angiography would show a displaced but patent artery. (Courtesy of Martin M. Malawer.)
FIG 3 • A. Osteosarcoma of the proximal humerus showing typical intramedullary ossification and an extraosseous soft tissue ossification. In general, a sarcoma of the proximal humerus involves one third to one half of the length of the bone. This length of bone must be resected in addition to the adjacent joint. B. Bone scan showing the amount of uptake corresponding to the radiograph shown in (A). In general, a resection is performed 3 to 4 cm distal to the area of uptake, as correlated with findings on an MRI scan, which is the imaging modality that best shows intramedullary extension of the tumor. C. Plain radiograph showing a radiolucent tumor of the proximal humerus. A needle biopsy confirmed that this was a giant cell tumor. CT shows minute fractures through the cortices, and the tumor was determined to be a stage III GCT. This patient was treated by primary resection of the proximal humerus. The procedure was classified as a type IA resection, and the humerus was reconstructed with an endoprosthetic modular prosthesis. Intra-articular resections are unusual for the proximal humerus, because most tumors are high grade with soft tissue components. D, E. Postoperative imaging studies are useful to determine response to induction chemotherapy. D. The CT scan shows complete reossification of a lesion of the proximal humerus without any major soft tissue component. The plain radiograph shows healing at the site of a former pathological fracture without any evidence of extraosseous formation. In general, CT scanning and plain radiography are reliable to demonstrate a good clinical response. E. Osteosarcoma of the proximal humerus, which does not show any evidence of an extraosseous component or any joint involvement. F. Schematic diagram of biopsy technique for tumors of the proximal humerus. The biopsy should be performed through the anterior one third of the deltoid, and the deltopectoral groove must be avoided. A core biopsy is recommended. (F: Reprinted with permission from Bickels J, Jelinek JS, Shmookler BM. Biopsy of musculoskeletal tumors. Current concepts. Clin Orthop Relat Res 1999;368:212–219.)
The most useful imaging studies are plain radiography, CT scans, MRI, arteriography, and bone scan. Venography occasionally is required.

**Computed Tomography**
- CT is most useful for evaluating cortical bone changes and is considered complementary to MRI in evaluating the chest wall, clavicle, and axilla for tumor extension (FIG 3D).

**Magnetic Resonance Imaging**
- MRI is useful to identify intraosseous tumor extent, which is necessary for determining the length of bone resection. It is the best imaging modality for evaluation of soft tissue tumor involvement, especially around the glenohumeral joint, suprascapular region, and chest wall.

**Bone Scintigraphy**
- Bone scintigraphy is used to determine the intraosseous tumor extent and to detect metastases (FIG 3B).

**Angiography**
- Angiography is extremely useful for evaluation of tumor vascularity and tumor response to neoadjuvant chemotherapy. It also is essential for determining the relation of the brachial vessels to the tumor or the presence of anatomic anomalies. A brachial venogram also may be necessary if there is evidence of distal venous obstruction suggesting a tumor thrombus.
- Repeat staging studies are typically performed following surgical resection to determine patient response to chemotherapy.

**Biopsy**
- Needle or incisional biopsies of tumors of the proximal humerus should be performed through the anterior one third of the deltid muscle, not through the deltoid interval (FIG 3F).
- A biopsy through the anterior one third of the deltoid results in a limited hematoma that is confined by the deltoid muscle.
- This portion of the muscle and any biopsy hematoma are easily removed at the definitive resection. A biopsy taken through the deltoid interval will contaminate the major pectoralis muscle, which is necessary for reconstruction, increase the risk of hematoma spread along the axillary vessels to the chest wall, and make a local resection difficult, if not impossible.
- If an open biopsy is required, a short longitudinal incision should be made just lateral to the deltoid interval. The dissection should be directly into the deltoid muscle and proximal humerus.
- The bone should be exposed lateral to the long head of the biceps. No flaps should be developed, and the glenohumeral joint should not be entered.

**Resection Techniques**
- It is important to be extremely familiar with shoulder girdle anatomy and axillary and vascular structures.
- A utilitarian incision is used (TECH FIG 1A–D). The anterior component is an extended deltopectoral incision that exposes the pectoralis major muscle, which is then released and retracted toward the chest wall. This exposes the axillary contents and permits exploration and safe dissection of the vascular structures and infraclavicular plexus (TECH FIG 1E).
- An extra-articular resection is performed. Thus, the axillary nerve is identified and transected. The musculocutaneous nerve is identified and preserved (TECH FIG 1F). The radial nerve, which crosses the humerus posteriorly at the level of the deltoid insertion, is preserved.

**Endoprosthetic Replacement of the Proximal Humerus**
- The Modular Replacement System (MRS), which is used for reconstruction of the shoulder girdle, is shown. Results of the MRS are predictable and successful, and the device is used for both intra- and extra-articular resections.
- Endoprosthetic reconstruction following tumor resection entails the following steps:
  1. Fixation of the endoprosthesis in the remaining distal humerus.
  2. Fixation and stabilization of the prosthetic humeral head to the scapula to provide a stable shoulder joint.
  3. Soft tissue reconstruction to cover the prosthesis completely and optimize postoperative function.

**Dual Suspension Technique**
- A dual suspension (ie, static and dynamic) technique is used to create shoulder stability (TECH FIG 4). In the static reconstruction, drill holes are made in the distal...
TECH FIG 1 • A. Utilitarian incision used by the authors for exposure of the proximal humerus, scapula, or shoulder girdle. B. The utilitarian approach is used for extra-articular resections of the shoulder girdle. Exposure of the anterior aspect and the axillary space routinely is performed by releasing two layers of muscle. The pectoralis major is released from its insertion onto the proximal humerus and reflected back onto the chest wall. This step exposes the entire axillary area, including the infraclavicular portion of the brachial plexus, the axillary artery and vein, the coracoid and scapula, and the corresponding muscles. C. Following reflection of the pectoralis major, the second muscle layer must be developed and detached and retracted. This layer consists of the pectoralis minor and the short head of the biceps. Each of these muscles has attachments to the coracoid. It is important to dissect the musculocutaneous nerve from around the coracoid as it enters the short head of the biceps to avoid nerve injury. These muscles are detached and retracted medially and distally, respectively, to expose the entire axillary fascia, which then can be opened to accomplish the following dissection. It is important to dissect the musculocutaneous nerve from around the coracoid as it enters the short head of the biceps. (continued)
TECH FIG 1 • (continued) D. Position and incision. Antibiotics are begun preoperatively and continued until suction drains are removed. The patient is placed in an anterolateral position that allows some mobility of the upper torso. A Foley catheter is placed in the bladder, and an intravenous line is secured in the opposite extremity. The skin is prepared down to the level of the operating table, to the umbilicus and cranially past the hairline. The incision starts over the junction of the inner and middle thirds of the clavicle. It continues along the deltopectoral groove and then down the arm over the medial border of the biceps muscle. The biopsy site is excised, leaving a 3-cm margin of normal skin. The posterior incision is not opened until the anterior dissection is complete. E. Exploration of the axilla to determine resectability. The skin is opened through the superficial fascia, but care is taken to preserve the deep fascia of muscles. Anteriorly, the skin flap is dissected off the pectoralis major muscle to expose its distal third, and the short head of the biceps muscle is uncovered. The pectoralis major muscle overlying the axilla is dissected free of axillary fat so that its insertion on the humerus can be visualized; this muscle is divided just proximal to its tendinous insertion on the humerus, and the portion of the muscle remaining with the patient is tagged with a suture. Next, the axillary sheath is identified and the coracoid process visualized. To expose the axillary sheath along its full extent, the pectoralis minor short head of the biceps and coracobrachialis muscles are divided at their insertion on the coracoid process. All proximal muscles are tagged with sutures for later identification and use in the reconstruction. (continued)
**TECH FIG 1 • (continued)**

**F.** Dissection of the neurovascular bundle. Vessel loops are passed around the neurovascular bundle near the proximal and distal ends of the dissection. Medial traction on the neurovascular bundle allows visualization of the axillary nerve, posterior circumflex artery, and anterior circumflex artery. These structures are ligated and then divided. If the neurovascular bundle is found to be free of tumor extension, dissection for the limb salvage procedure proceeds. The musculocutaneous nerve is isolated and carefully preserved, although this nerve sometimes must be sacrificed to preserve tumor-free margins. Its loss results in lack of elbow flexion following surgery. The deep fascia between the short and long heads of the biceps muscle is divided below the tumor mass to separate the short and long heads of the biceps maximally, permitting easy visualization of the musculocutaneous nerve. The radial nerve is identified at the lower border of the latissimus dorsi muscle, passing around and behind the humerus into the triceps muscle group. The profunda brachialis artery that accompanies this nerve may be ligated. The radial nerve passes posterior to the humerus in its midportion (spiral groove). To dissect it free of the bone, a finger is passed around the humerus to bluntly move the nerve away from the bone. **G.** Division of the muscle groups anteriorly to expose the neck of the scapula. The short and long heads of the biceps are widely separated to expose the humerus. The site for the humeral osteotomy is determined, and then the long head of the biceps and brachialis muscles are transected at this level. The inferior border of the latissimus dorsi muscle is identified, and a fascial incision is made that allows one to pass a finger behind the latissimus dorsi and teres major muscles several centimeters from their insertion into the humerus or scapula. The latissimus dorsi and teres major muscles are transected using electrocautery. External rotation of the humerus exposes the subscapularis muscle, which is transected at the level of the coracoid process. Care must be taken not to enter the joint space. The portions of these muscles that are not to be removed during the resection are tagged for future reconstruction. By transecting these muscles the anterior portion of the neck of the scapula has been exposed. (**C,D,F,G:** Courtesy of Martin M. Malawer; **E:** Reprinted with permission from Malawer MM. Tumors of the shoulder girdle. Technique of resection and description of a surgical classification. Orthop Clin North Am 1991;22:7–35.)
Chapter 10 PROXIMAL HUMERUS RESECTION WITH ENDOPROSTHETIC REPLACEMENT

**TECH FIG 2** Various methods used for reconstruction of the proximal humerus following resection for high-grade sarcomas between 1960 and 1990. **A.** The first attempts to regain length used the Kirschner rod fixated into the distal humerus and sutured to the clavicle with wires or heavy sutures. This failed, and often caused proximal protrusion through the skin. **B.** The long-stemmed Neer prosthesis was developed to re-establish humerus length and to avoid the problem of proximal migration. **C.** The first custom prosthesis, developed in the mid-1970s to reconstruct the proximal humerus in an anatomic format. This had both external phlanges and a small stem. **D.** The Modular Replacement System (Stryker Orthopedics, Mahwah, NJ) is the type of prosthesis currently used. A modular replacement system has a head, body, and stem of various diameters and lengths so that it can be modified intraoperatively for each patient’s anatomic needs. No waiting period for a custom prosthesis to be made is required, as formerly was the situation. The first proximal humerus prosthesis of the MRS type was implanted in Washington, DC in 1988. (**A–D:** Courtesy of Martin M. Malawer.)

Soft Tissue Reconstruction

- The remaining muscle groups are tenodesed to the pectoralis major and osteomized border of the scapula with Dacron tape. This mechanism offers dynamic support, assists in the suspension of the prosthesis, and provides soft tissue coverage. Soft tissue coverage is essential to cover the prosthesis and prevent skin problems and secondary infections.

**Type I Resection**

- Intra-articular resection of the proximal humerus is indicated for low-grade sarcomas or high-grade sarcomas confined to the bone without extraosseous extension (stage IIA; **TECH FIG 5A,B**).
- The abductor mechanism and axillary nerve usually are preserved. This procedure is not recommended for high-grade sarcomas with soft tissue extension.
- The prosthesis is suspended from the glenoid with a Gore-Tex graft, which is reinforced by any remaining capsule (**TECH FIG 5C–E**).
- Anterior utilitarian shoulder incision is not required. The posterior component is not used.
TECH FIG 3 • A. Securing the prosthesis. If a prosthesis is to be used, 5 to 7 cm of distal humerus must be preserved. A power reamer is used to widen the medullary canal of the remaining humerus; it is reamed until it is 1 mm larger than the stem of the prosthesis. The bony specimen is measured so that a prosthesis of appropriate length is used. Methylmethacrylate cement is injected into the medullary canal, and the prosthesis is positioned. The head of the prosthesis should be oriented so that it lies anterior to the transected portion of scapula while the arm is in neutral position. The radial nerve should be positioned anterior to the prosthesis so it does not become entrapped between muscle and prosthesis during the reconstruction. Drill holes are made through the scapula at the level of its spine, and also through the distal portion of the transected clavicle. The head of the prosthesis is secured by 3-mm Dacron tape to the remaining portion of the scapula so that the prosthesis is suspended mediolaterally, providing horizontal stability. It is suspended in a cranio-caudal direction by a second 3-mm Dacron tape from the end of the clavicle, for vertical stability. B. Reconstruction. The pectoralis minor muscle is sutured to the subscapularis muscle over the neurovascular bundle to protect it from the prosthesis. The pectoralis major muscle is closed over the prosthesis to the cut edge of the scapula and secured with nonabsorbable sutures through drill holes. Following this the trapezius, supraspinatus, infraspinatus, and teres minor muscles are secured to the superior and lateral borders of the transected pectoralis major muscle. The teres major and latissimus dorsi muscles are secured to the inferior border of the pectoralis major muscle. The tendinous portion of the short head of the biceps is secured anteriorly under appropriate tension to the remaining clavicle. The long head of the biceps and the brachialis muscles are sutured to the short head of the biceps muscle under appropriate tension so that these two muscles can work through the short biceps tendon. The remaining triceps muscle is secured anteriorly along the lateral border of the biceps to cover the lower and lateral portion of the shaft of the prosthesis. Ideally, when the proximal and distal muscular reconstruction is complete the prosthesis is covered in its entirety by muscle. C. Closure. Large-bore suction catheter drainage is secured. The superficial fascia is closed with absorbable suture, and the skin is closed with clips. Povidone-iodine ointment is applied to the incision along with a dry sterile dressing. A sling and swathe are applied in the operating room. (A,B: Reprinted with permission from Rubert CK, Malawer MM, Kellar KL. Modular endoprosthetic replacement of the proximal humerus: Indications, surgical technique, and results. Semin Arthroplasty 1999;10:142–153. C: Courtesy of Martin M. Malawer.)
The axillary nerve is explored early and preserved. If there is tumor extension to the nerve, then the procedure is converted to a type V resection.

The humeral prosthesis is suspended from the glenoid labrum with 32-mm Gore-Tex®. The remaining capsule is sutured to the new Gore-Tex® capsule. This step avoids glenohumeral joint subluxation and dislocation.

**Total Humeral Resection and Prosthetic Reconstruction**

Total humeral replacement is unusual but is indicated when the tumor involves a large portion of the diaphysis, such as in Ewing sarcoma, or when an extremely short segment of distal humerus remains following adequate tumor resection.

The surgical technique is a combination of that used for proximal and distal humerus resections. Reconstruction provides stability of both shoulder and elbow joints.

**Exposure and Extension of Type V Procedure (TECH FIG 6)**

The surgical approach is similar to that used for a type V resection (ie, anterior utilitarian approach), but it requires additional distal exposure and identification and mobilization of the brachial artery and vein and the radial, ulnar, and median nerves.

The incision and exposure are continued down the anteromedial aspect of the arm, across the antecubital fossa, and, if necessary, down the anterior aspect of the forearm. The brachial vessels, along with the median and ulnar nerves, are identified medially in the arm.

The medial intermuscular septum is transected to allow further dissection and mobilization of the ulnar nerve so that it can be retracted medially with the brachial vessels and median nerve.

The biceps is retracted medially with the neurovascular bundle. The radial nerve is identified where it passes around the humerus and into the interval between the brachialis and brachioradialis muscles and continues into the forearm.

The pronator teres and common flexor origins are transected medially, and the brachioradialis, extensor carpi radialis longus, and common extensor origins are released laterally to expose the distal humerus. A small cuff of muscle is left around the tumor as needed. The medial triceps muscle usually is resected with the tumor, but the lateral and long heads are retained. The triceps tendon is kept attached to the olecranon. The olecranon is not osteotomized. The elbow joint is opened anteriorly and the capsule released circumferentially. The humero-ulnar and radiohumeral joints are then disarticulated.

**Prosthetic Reconstruction, Muscle Reconstruction, and Postoperative Management**

Reconstruction of the total humerus is similar to that of the proximal humerus. Distally, an ulnar endoprosthetic component with an intramedullary stem is cemented, with the olecranon left intact. Several articulating elbow devices are available.

The reconstruction technique is similar to that used for the proximal humerus, with the addition of distal soft tissue and joint capsule reconstruction.

The brachioradialis, pronator teres, and flexor carpi radialis muscles are sutured to the remaining biceps and triceps muscles to secure soft tissue around the flared distal portion of the humeral endoprosthesis.

The remaining muscles are closed in layers in an attempt to cover the entire prosthesis.

A posterior splint is used to protect the elbow reconstruction for 7 to 10 days. The surgical incision and wounds are examined on the fourth to fifth postoperative day.
Intraoperative photographs of an intra-articular resection. A. The tumor has been removed, demonstrating the relation of the axillary nerve to the capsule and the glenoid. The brachial vessels have been mobilized and are seen in the vessel loop. The structures around the proximal humerus are in close proximity to the subscapularis muscle and the joint capsule. These vessels are initially identified and retracted prior to resection. B. Reconstruction of the proximal humerus is performed with the MRS. It is essential to reconstruct the capsule, because soft tissue reconstruction alone will not maintain any stability either of the humeral head or to the shallow glenoid. Therefore, a Gore-Tex graft is used and is sutured to the rim of the glenoid. The humeral head then is reduced within this sleeve and sutured, using Dacron tape, through holes in the humeral head. This is the technique routinely used for intra-articular resections of the proximal humerus. C–E. Schematic of a proximal humerus reconstruction with static and dynamic transfers as well as a proximal humeral prosthesis. This technique, which has been used by Malawer since 1988, provides excellent coverage of the prosthesis and stability with active motion of the new glenohumeral joint. The prosthesis is suspended from the remaining axillary border of the scapula with two Dacron tapes, and with additional tapes from the prosthesis to the clavicle. Therefore, both longitudinal and horizontal stabilizing forces are in place. The soft tissue reconstruction consists of the long head of the biceps being attached to either the clavicle or the transferred pectoralis major muscle. The prosthesis is covered with four muscles. The pectoralis major and subscapularis muscles are sutured over the prosthesis to the remaining border of the scapula through drill holes using Dacron tape. This provides immediate stability and good coverage of the prosthesis. The prosthetic head is placed anterior to the scapula, not at the lateral border, and is then placed in the subscapular fossa. The remaining muscles of the teres and the infraspinatus are brought anteriorly and sutured, and the trapezius muscle is mobilized at the base of the neck to the area of muscle reconstruction. (C–E: Reprinted with permission from Rubert CK, Malawer MM, Kellar KL. Modular endoprosthetic replacement of the proximal humerus: Indications, surgical technique, and results. Semin Arthroplasty 1999;10:142–153.)
This chapter contains a complete description of the technique for a modified Tikhoff–Linberg procedure in patients with sarcomas of the proximal humerus. Modifications of the procedure also have been used for tumors at other anatomic sites. Proximal humeral lesions require resection of about two thirds of the humerus. The technique of resection and reconstruction requires a thorough knowledge of the regional anatomy and technique of musculoskeletal reconstruction. Essential aspects of the treatment plan should be emphasized.

- This initial biopsy should be performed through the anterior portion of the deltoid muscle for a lesion of the proximal humerus. The deltopectoral interval should not be used, because biopsy here would contaminate the deltopectoral fascia, the subscapularis, and the pectoralis major muscles, and would jeopardize the possibility of performing an adequate resection through uninvolved tissue planes.

For the definitive resection, the initial incision extends along the medial aspect of the biceps muscle, divides the pectoralis major, and exposes the neurovascular structures, thereby enabling the surgeon to determine resectability early in the dissection.

This incision does not jeopardize construction of an anterior skin flap in patients who will require forequarter amputation.
Resection

- The length of bone resection is determined preoperatively from a bone scan and MRI. To avoid a positive margin at the site of humeral transection, the distal osteotomy is performed 3 to 5 cm distal to the area of abnormality on the scan.
- Alternatively, other surgeons use autografts (usually fibulas) or allografts as spacers in obtaining an arthrodesis. We do not recommend osteoarticular allografts or intra-articular resections for high-grade bone sarcomas; those techniques were developed during the 1960s and 1970s and are inferior to current standards. Superior results routinely are obtained with modular prosthetic replacements combined with reconstruction of the soft tissues (FIG 4).

Reconstruction

- Segmental reconstruction of the resultant humeral defect is necessary to create shoulder stability. We do not leave a flail extremity. Reconstruction is necessary to maintain length of the arm and to create a fulcrum for elbow flexion. We recommend a custom or modular prosthesis.
- The key to success is reconstruction of the stability of the joint and soft tissue coverage of the prosthesis.

FIG 4 • Original photograph taken following an extra-articular resection of a large section of the proximal humerus and scapula involved by an osteosarcoma during the late 1960s. This was one of the first shoulder girdle resections performed in the United States. Notice the marked shortening of the limb, but the fairly normal functioning of the hand and elbow. Subsequently, multiple techniques have been utilized to maintain the length and function of the shoulder girdle. (Courtesy of Ralph C. Marcove, MD.)

REFERENCES

BACKGROUND
- The distal humerus is a relatively rare site for primary bone sarcomas. It is more commonly involved by neoplasm through metastatic spread. The distal humerus or elbow joint also can be secondarily involved by soft tissue sarcomas arising from the adjacent musculature or intermuscular soft tissues. Sarcomas that arise from the most proximal portions of the flexor–pronator group or common forearm extensor muscles may involve the distal humerus by direct invasion or by growing around the circumference of the distal humerus. Sarcomas that arise from the distal brachialis muscle or triceps muscle also may secondarily involve the distal humerus.
- Tumors arising in this area that involve the soft tissues are technically challenging to resect. These tumors usually are juxtaposed to and displace the adjacent neurovascular structures that lie in immediate proximity to the distal humerus and within the antebrachial fossa.
- The key to a safe and successful resection lies in identifying and mobilizing all important neurovascular structures (eg, brachial artery and vein, median nerve, ulnar nerve, and radial nerve) away from the neoplasm and distal humerus. The biceps muscle must be preserved in order to restore elbow flexion after reconstruction.
- Each of the neurovascular structures is identified proximal to the tumor, in normal tissue, in the distal one third of the arm. These structures are dissected in a proximal-to-distal direction, separated from the neoplasm, and mobilized across the elbow joint. Once these structures are mobilized and protected, it is safe to proceed with removing the distal humerus and tumor en bloc.
- In most cases, even the most extreme cases, the neurovascular structures are displaced and not encased by neoplasm, making limb-sparing surgery an option in lieu of an amputation (FIG 1). Gross tumor involvement of a single nerve is not an absolute indication for an above-the-elbow amputation. Involvement of more than one major nerve or the main vascular supply is an indication for an above-the-elbow amputation when treating a sarcoma with curative intention. In cases of metastatic carcinomas, where treatment is palliative, adjuvant treatments such as radiation or chemotherapy should be considered before proceeding with an amputation.
- Prosthetic reconstruction of the distal humerus and elbow joint with a modular, segmental, tumor prosthesis including a semiconstrained, hinged elbow joint is a reliable means of skeletal reconstruction following resection. Multiple muscle rotation flaps, retensioning the biceps muscle, and flexorplasty of the forearm musculature are key steps to restoring elbow flexion power.

ANATOMY
Neurovascular Structures
- In the middle one third of the arm, most of the important neurovascular structures lie within a fibrous sheath, in the groove between the biceps and triceps muscles, along the medial side of the arm, just medial to the brachialis muscle. These structures include:
  - The brachial artery, which is surrounded by two small brachial veins
  - The median nerve, which lies directly anterior to the brachial artery
  - The cephalic vein and medial antebrachial cutaneous nerve, which lie superficial to the brachial artery
  - The ulnar nerve, which is surrounded by the superior ulnar recurrent artery and two veins that lie just medial and posterior to the brachial artery
  - The medial brachial cutaneous nerve, which lies in the superficial subcutaneous tissue at this level.
- At this level, the radial nerve lies within the spiral groove of the humerus along the posterolateral aspect of the arm.
- The brachial artery and veins are the continuation of the axillary artery and vein at the level of the lower border of the subscapularis muscle. The brachial artery and veins travel distally along the medial side of the arm, deep to the fascia, in the interval between the biceps and triceps muscles, medial to the brachialis muscle.
- The profunda brachii artery arises proximally from the brachial artery at the lower border of the latissimus dorsi muscle. It traverses dorsally and laterally with the radial nerve and enters the spiral groove.
- The brachial artery gives off several branches along its course to the biceps, brachialis, and triceps muscles. In the antebrachial fossa, the brachial artery lies on the anterior surface of the brachialis muscle, immediately adjacent and lateral to the median nerve. The brachial artery passes just deep to the bicipital aponeurosis to enter the forearm. The inferior ulnar collateral artery arises from the brachial artery just proximal to the bicipital aponeurosis and passes medially just along the proximal aspect of the medial condyle of the humerus. After the brachial artery passes underneath the bicipital aponeurosis, it branches into the ulnar artery, radial recurrent artery, and radial artery.
- The median nerve travels distally in the arm, closely applied to the anterior aspect of the brachial artery. As the median nerve approaches the antebrachial fossa, it crosses over medially so that it occupies a position immediately medial to the brachial artery and lateral to the pronator teres muscle in the antebrachial fossa.
- The ulnar nerve occupies a position slightly more medial and posterior to the brachial artery in the mid-arm. In the distal one third of the arm, the ulnar nerve travels posteriorly and pierces the medial intermuscular septum. It travels along the medial side of the triceps muscle and enters a groove (cubital tunnel) along the posterior aspect of the medial epicondyle of the humerus. The ulnar nerve is tethered within this groove by ligamentous tissue. It then travels distally and enters the forearm by passing through the humeral and ulnar heads of the pronator teres muscle. In the forearm, the ulnar nerve lies along the deep surface of the flexor carpi ulnaris muscle.

PROSTHETIC RECONSTRUCTION
- Prosthetic reconstruction of the distal humerus and elbow joint with a modular, segmental, tumor prosthesis including a semiconstrained, hinged elbow joint is a reliable means of skeletal reconstruction following resection. Multiple muscle rotation flaps, retensioning the biceps muscle, and flexorplasty of the forearm musculature are key steps to restoring elbow flexion power.
The medial antebrachial cutaneous nerve is a small nerve that lies deep to the fascia between the median and ulnar nerves at the mid arm level. In the distal one third of the arm, the nerve occupies a more superficial position in the subcutaneous tissue.

The radial nerve arises from the posterior cord of the brachial plexus. At the inferior border of the latissimus dorsi muscle, the radial nerve passes posteriorly, along with the profunda brachii artery, through the interval between the long head of the triceps and the humerus. The radial nerve enters the spiral groove of the humerus and travels distally, wrapping around the posterior aspect of the humerus, in the interval between the medial and lateral heads of the triceps muscle. In the distal one third of the arm, the radial nerve passes through the lateral intermuscular septum and enters the anterior compartment of the arm, where it resides in the interval between the brachioradialis muscle and brachialis muscle. The radial nerve continues distally into the forearm. At the lower, lateral border of the brachialis muscle, just proximal to the supinator muscle, the radial nerve divides into the posterior interosseous nerve and the superficial radial nerve. The posterior interosseous nerve passes through the substance of the supinator muscle. The superficial radial nerve travels distally along the deep surface of the brachioradialis muscle.

INDICATIONS AND CONTRAINDICATIONS

Indications for Surgical Resection

- High-grade and some low-grade bone sarcomas
- Soft tissue sarcomas that surround or invade the distal humerus or elbow joint secondarily
- Solitary metastatic carcinomas to the distal humerus
- Metastatic carcinomas that have destroyed a significant portion of the distal humerus, which precludes other methods of resection and fixation
- Local complications resulting from other treatments for tumors involving the distal humerus, eg, nonunion of a pathological fracture following radiation

Contraindications to Surgical Resection

- Absolute contraindications include tumor involvement of the neurovascular bundle.
- Involvement of a single major nerve is not an absolute contraindication. The nerve can be resected with the neoplasm.
- Encasement of the brachial artery and veins or two or more major nerves usually precludes a limb-sparing resection.
- Final determination regarding the need for an amputation is made at the time of surgery, after the neurovascular structures are explored. Adjuvant treatments such as radiation and chemotherapy should be considered for palliation of metastatic carcinomas prior to proceeding with an amputation.
- Relative contraindications include tumor contamination of the operative site from hematoma following a poorly performed biopsy or pathologic fracture or a previous or active infection. Recently, we have successfully treated patients with pathologic fractures with induction chemotherapy, immobilization, and limb-sparing surgery if there is a good clinical response and fracture healing; survival has not been compromised, and local recurrence is less than 10%.

IMAGING AND DIAGNOSTIC STUDIES

- The most useful imaging studies are plain radiography, CT, MRI, arteriography, and bone scan. These studies are useful for diagnosis, evaluating local and distant extent of disease, and, for select sarcomas, gauging the response to preoperative chemotherapy. Radiologic studies are necessary to determine the exact anatomic extent of the neoplasm so that the surgical procedure can be planned accurately.

Plain Radiographs

- Plain radiographs of the humerus and elbow are used to localize the anatomic origin of the tumor, formulate a differential diagnosis, and estimate tumor extent (FIG 2A).
- After preoperative chemotherapy for an osteosarcoma, plain radiographs can be used to estimate the response of the tumor to the chemotherapeutic agents. A good response (> 90% tumor necrosis) is indicated by extensive tumor calcification, periosteal new bone formation, and healing of pathologic fractures.

Computed Tomography

- CT is most useful for evaluating cortical bone changes and extent of cortical destruction by tumor. In the case of a metastatic carcinoma, it aids with decision making regarding the indication for a resection and prosthetic reconstruction versus curettage and internal fixation. Extensive cortical destruction throughout a significant circumference of the bone is an indication to proceed with a resection of the distal humerus and prosthetic reconstruction.
- CT also is useful for detecting subtle mineralization, calcification, or ossification within the neoplasm that may assist in diagnosis.
- CT is considered complementary to MRI in evaluating the soft tissue component of the neoplasm and proximity to the neurovascular structures, particularly a contrast-enhanced CT scan.
- CT also assists with detection of subtle cortical erosion and frank invasion of the distal humerus by adjacent soft tissue sarcomas that may not be clearly delineated on MRI or plain radiographs.
- After preoperative chemotherapy of an osteosarcoma, CT characteristically shows a rimlike calcification in those tumors that have had a good response.
- Chest CT is most sensitive for detecting lung metastases.
Magnetic Resonance Imaging

- MRI is most accurate for determining intra- and extracortical tumor extent as well as for detecting skip metastases. An appreciation of intraosseous extent is necessary for determining the length of bone resection.
- The humerus usually is transected approximately 2 to 3 cm proximal to the intramedullary extent of the neoplasm as visualized on a T1-weighted MRI scan.
- Proximity of the extraosseous component to the brachial vessels, median nerve, ulnar nerve, and radial nerve also can be evaluated, as can secondary involvement of the distal humerus and elbow joint by adjacent soft tissue sarcomas.
- Standard T1-weighted, T2-weighted, fat-suppressed, and gadolinium-enhanced images are recommended (FIG 2B).

Bone Scintigraphy

- Bone scintigraphy is used to determine intraosseous tumor extent and is compared to the MRI scan to ensure accuracy. It also is used to detect bony metastases and skip metastases.

Thallium Scintigraphy

- Thallium 201 is a potassium analog that is actively transported by the sodium–potassium ATPase pump. A quantitative thallium scan has been useful for determining viability of bone tumors, particularly osteosarcomas.
- The affected side is compared to the unaffected side; a ratio below 4:1 is consistent with tumor necrosis greater than 90% (a good response).

Angiography

- Angiography is extremely useful for evaluation of tumor vascularity and is considered the gold standard for evaluating tumor response to neoadjuvant chemotherapy. High grade sarcomas, such as osteosarcoma, demonstrate a tumor blush on an arteriogram when viable (fill with contrast dye because of extensive neovascularization of the tumor). The neovascularization and hence the tumor blush disappear when the tumor has had a good response to a preoperative chemotherapy regimen.
- It is also essential for determining the relationship of the brachial vessels to the tumor or the presence of anatomic anomalies. The soft tissue component of distal humeral tumors routinely displaces the brachial vessels. Soft tissue sarcomas that arise around the distal humerus also usually routinely displace the brachial vessels. The direction in which these structures are displaced can be determined with a biplanar arteriogram.

Biopsy

- Needle or incisional biopsies of tumors of the distal humerus should be performed through the brachialis muscle in line with the proposed skin incision so the biopsy tract can be excised at the time of the definitive procedure.
- The biopsy should never be performed through the biceps muscle; it should, rather, be performed along either side of the muscle. The biceps must be spared in order to be able to reconstruct the distal humerus and preserve elbow flexion.
- In general, the biopsy is best made directly anterior, just lateral to the biceps tendon or distal biceps muscle, close to the antecubital crease. In this manner, the biopsy tract can be excised with the transverse portion of the incision that crosses the antecubital crease.
- Occasionally, a very large soft tissue component that protrudes anteriorly and medially will displace the neurovascular structures medially. In these instances, it may be possible to biopsy the tumor, under CT guidance for visualization of the neurovascular structures, just medial to the medial margin of the distal biceps muscle or biceps tendon. The tumor will occupy a subcutaneous position in this location and is easily biopsied. With either approach it is important to perform the biopsy through the brachialis muscle and to avoid contaminating the biceps muscle. The portion of the brachialis muscle and biopsy hematoma are easily removed at the definitive resection.
- Biopsy of a tumor arising from the brachioradialis or common extensor muscle origin is performed anteriorly, directly over the mass, along the lateralmost 1 to 2 cm of the antecubital crease. Extreme care is taken to avoid contaminating the radial and posterior interosseous nerves.
- Biopsy of a tumor arising from the flexor–pronator muscle group is performed at the most medial extent of the antecubital crease, directly over the mass and at a distance from the median nerve and brachial artery.
SURGICAL MANAGEMENT

Preoperative Planning

- Staging studies are thoroughly reviewed before the surgical procedure.
- The T1-weighted coronal MRI scan of the entire humerus is reviewed. The length of the bone resection is based primarily on this study. The transection level is determined so that it will permit a 2 to 3 cm margin proximal to the intraosseous tumor extent. In the case of an adjacent soft tissue sarcoma, the bone is transected 2 cm to 3 cm proximal to the soft tissue involvement of the humerus. Surgical resection is modified to account for skip metastases, both intraosseous and transarticular. The length of the resection can be determined preoperatively to ensure all components of the prosthesis needed for reconstruction will be present. Nowadays, modular segmental prostheses are utilized that are assembled intraoperatively. The size can be adjusted intraoperatively to accommodate for the resection.
- The MRI and CT scans are reviewed to evaluate the exact degree of soft tissue extension and proximity to the neurovascular structures. CT and MRI results are evaluated to determine areas of the distal humerus or elbow joint that may be directly involved by an adjacent soft tissue sarcoma.
- The arteriogram provides a “road map” showing the direction of displacement of the neurovascular structures and also alerts the physician to any anomalies that may be encountered during surgery.
- Flexible reamers, sagittal saw, drill or high-speed burr, osteotomes, cement, cement gun, ball-tip guide wire, no. 5 non-absorbable sutures, vessel loops, and 1/4-inch Penrose drain will be required.

Positioning

- The patient is placed in a supine position with the arm abducted and placed on a padded and draped Mayo stand. A small bump is placed under the ipsilateral scapula, to elevate the shoulder girdle slightly off the bed. The entire upper extremity, from the middle of the clavicle and shoulder girdle through the fingertips, is prepped and draped in a sterile manner.

Approach

- A limb-sparing distal humeral resection has three major components:
  - Oncologic resection
  - Skeletal reconstruction
  - Soft tissue reconstruction or coverage (or both).
- The goal of the resection is to remove the entire tumor en bloc or, in other words, in one piece with the distal humerus. The key to the resection involves meticulously dissecting, separating, and mobilizing the important neurovascular structures away from the neoplasm.
- Skeletal reconstruction is done with a modular, segmental replacement that can be assembled and have its size adjusted intraoperatively. The length of the prosthesis may be downsized as much as a few centimeters to facilitate soft tissue coverage of the prosthesis, if necessary.
- Soft tissue reconstruction that involves rotating and reattaching muscles and restoring the length–tension relationship of the forearm muscles and biceps is most important for achieving a good functional result and for protecting the prosthesis from infection.

DISTAL HUMERAL RESECTION

- The S-shaped incision begins in the middle of the arm along the medial side of the biceps muscle (TECH FIG 1A,B). It is extended distally along the medial border of the biceps muscle to the antecubital crease; the biopsy tract is included in the incision in an elliptical manner. At the antecubital crease, the incision curves laterally along the volar aspect of the elbow to the volar margin of the brachioradialis muscle, where it then turns distally and is extended distally along the forearm for a short distance.
- Medial and lateral cutaneous flaps are raised (TECH FIG 1C,D). Wherever possible, fasciocutaneous flaps are raised. Medial and lateral antebrachial cutaneous nerves are preserved.
- Proximally in the arm (proximal to the neoplasm in normal-appearing tissues), in the interval between the biceps and triceps muscles, the neurovascular structures are identified within their sheath. The deep investing fascia of the arm (superficial layer of the sheath) is opened longitudinally directly over these structures. While protecting the underlying structures, the fascia is opened from proximally to distally all the way down to the neoplasm or antecubital fossa. The neurovascular structures can be visualized easily, and the brachial artery can be palpatied once the sheath is opened. Proximally, the brachial artery and accompanying veins are isolated and surrounded with a vessel loop. Likewise, the median, ulnar, and medial antebrachial cutaneous nerves are each identified, isolated, and individually surrounded with a vessel loop.
- The brachial artery and veins are meticulously dissected away from the surrounding tissues and from the pseudo-capsule of the neoplasm down to and across the antecubital fossa. The biceps aponeurosis is incised to permit visualization of the brachial artery to the point where the ulnar and radial arteries arise. The radial and ulnar arteries are each identified and surrounded with a vessel loop. The inferior ulnar collateral vessels, as well as muscular branches to the biceps, brachialis or triceps muscle, may require ligation to mobilize the brachial vessels away from the neoplasm, depending on the location and position of the tumor. Once the artery is freed from the neoplasm, attention is turned to mobilizing the major nerves.
- The median nerve is dissected from a proximal to distal direction across the antecubital fossa, where it lies just medial to the brachial artery. It is dissected distally to where the anterior interosseous nerve arises from it and the median nerve continues deep to the flexor digitorum superficialis muscle.
- The ulnar nerve also is isolated and dissected from a proximal to distal direction. The medial intermuscular septum is opened to allow further dissection and mobilization of the ulnar nerve to the cubital tunnel along the medial
TECH FIG 1 • A. An anterior surgical incision is routinely used for resection and prosthetic replacement of the elbow joint and distal humerus. The surgeon can palpate the normal anatomic structures. The longitudinal incision is made along the biceps–triceps interval. The joint is exposed through an S extension of the proximal incision. B. Schematic drawing of the anterior exposure. The neurovascular structures are identified (ie, brachial artery, median nerve, radial nerve, ulnar nerve) and retracted. This is essential for a safe procedure. C. Wide medial and lateral flaps are required for adequate exposure. D. The biceps as well as the neurovascular structures are retracted.

**Epicondyle of the Distal Humerus.** The fascia or ligamentous tissue overlying the cubital tunnel is opened longitudinally, and the ulnar nerve is gently mobilized from the tunnel all the way to where the nerve passes between the humeral and ulnar heads of the pronator teres muscle. This enables the ulnar nerve to be retracted medially with the brachial vessels and median nerve.

- The radial nerve is identified in the interval between the brachioradialis and brachialis muscles. It is dissected distally across the elbow joint to the juncture where the posterior interosseous nerve originates from the radial nerve. It also is dissected proximally as it passes through the lateral intermuscular septum around the posterior aspect of the humerus in the spiral groove. The lateral intermuscular septum is opened, and the radial nerve is mobilized away from the posterior aspect of the humerus up to the latissimus dorsi muscle insertion.
- The biceps muscle is isolated, dissected away from neoplasm and the underlying brachialis muscle. Usually, the biceps is not involved by any neoplasm. If it is involved, a portion may require removal. (Be aware that the biceps or brachialis muscle is required for elbow flexion; removal of both in entirety prohibits elbow flexion postoperatively.) The biceps muscle is isolated so it can be retracted medially and laterally when necessary.
- The pronator teres and common flexor muscles are released from their origins from the distal humerus medially. The brachioradialis, extensor carpi radialis longus, and common extensor muscles are released laterally from the distal humerus. A small cuff of muscle is left around the tumor as needed. Occasionally, a distal humerus resection is performed for a soft tissue sarcoma that originates from one of these muscle groups. In such a case, the muscle or muscles that are involved by neoplasm are transected distally to the tumor in such a manner that an adequate margin is maintained. When resecting the flexor-pronator group, the branch of the median nerve that supplies the flexor digitorum superficialis is identified and protected, if possible. On the lateral side of the elbow, if the brachioradialis and common extensor muscles require resection, the posterior interosseous nerve is identified and protected to preserve wrist and digit extension.
- A portion of the brachialis muscle, or even the entire brachialis muscle, may require resection, depending on the extent of the tumor. If there is no soft tissue component arising from a distal humerus tumor or if the brachialis muscle is not involved by an adjacent soft tissue sarcoma, then the brachialis muscle is incised longitudinally along the anterior aspect of the distal humerus. The brachialis muscle is then elevated off the

TECHNIQUES

**TECH FIG 2** • A. The appropriate length of resection is determined preoperatively from the MRI scan. In general, a 2- to 3-cm margin of normal bone is removed. B. Schematic drawing of the resection defect. C. Operative photograph of the surgical defect. Note the wide exposure. This is required for accurate positioning of the prosthesis and reaming of the ulnar canal. The triceps remains attached to the surrounding soft tissues.

Distal humerus and preserved. If there is a soft tissue component arising from a tumor of the distal humerus or if the brachialis muscle is involved by an adjacent soft tissue sarcoma, then the brachialis muscle is released in a subperiosteal manner from its insertion on the ulna or simply transected distal to the elbow joint.

- The triceps muscle is elevated off the distal humerus and may require partial or complete resection of the medial head, depending on tumor extent. The lateral and long heads usually can be preserved. The triceps tendon is kept attached to the olecranon. The olecranon is not osteotomized.
- The elbow joint is opened anteriorly and the capsule released circumferentially from the ulna–olecranon and radial head. The humero-ulnar and radiohumeral joints are then disarticulated.
- The humerus is osteotomized at a level approximately 2 to 3 cm proximal to the intramedullary extent of the neoplasm (TECH FIG 2A). The area where the humerus will be osteotomized is cleared of overlying brachialis muscle and triceps muscle. The radial nerve is identified and protected before cutting the bone. The bone usually is transected with a sagittal saw (TECH FIG 2B,C).

**PROSTHETIC RECONSTRUCTION**

- Reconstruction of the distal humerus and elbow joint is performed with a modular segmental distal humerus tumor prosthesis. The distal humeral component consists of a semiconstrained hinge component that is attached to an ulnar component to recreate the elbow joint.
- Proximally, the distal humeral component can be fit to a body segment via a Morse taper. The body segment is available in different lengths, so the size can be adjusted intraoperatively. The body segment is fit to a stem via a Morse taper. The stem then is cemented into the more proximal remaining humeral canal.
- The ulnar component consists of a stem that is cemented into the olecranon and proximal ulna. The ulna component is available in two lengths.
- The length of the prosthesis is chosen. It may be downsized 2 to 3 cm to help facilitate soft tissue closure. The prosthesis is assembled on the field.
- The remaining humerus is flexibly reamed to accommodate as wide a stem as possible. It is overreamed 1 to 2 mm to accommodate for a cement mantle. The olecranon fossa is opened with a small high-speed burr (TECH FIG 3) to enter into the medullary canal of the proximal ulna. The proximal tip of the olecranon is shaved slightly to accommodate the ulna stem, so that it can be inserted directly into the ulnar canal without being inserted on an angle. The canal of the ulna is reamed with hand reamers. Trial components are available to be used to ensure that the ulna component will sit properly within the medullary canal of the proximal ulna.
- Both components are cemented into place separately. The distal humerus is cemented so the hinge will face anteriorly. It is important to identify the anterior surface of the humerus before the distal humeral component is inserted. The ulna component is placed so that it sits as deep as possible within the olecranon fossa without
TECH FIG 3 • Technique of preparing the ulnar notch. A high-speed burr is recommended.

Soft tissue closure.

A. It is important for the prosthesis to be completely covered by muscle. The flexors (from the medial condyle) and the brachioradialis (mobile wad of 3) from the lateral condyle are reattached to the adjacent soft tissue. It is not necessary to attempt reattachment to the prosthesis.

B. Reattachment of the elbow flexors. An ulnar nerve transposition may be performed, although this is not done routinely. The passive range of motion of the elbow is tested prior to closure. If there is any restriction, the radial head should be examined or removed.

C. The origin of the flexor–pronator forearm muscles also is transferred as far proximal as possible and sutured to the medial border of the biceps and triceps muscles.

Soft tissue and muscle reconstruction

- The brachioradialis and extensor carpi radialis muscles are sutured to the remaining biceps and triceps muscles to secure soft tissue around the flared distal portion of the humeral endoprosthesis. A flexorplasty is performed. With the elbow held in 60 degrees of flexion and the forearm fully supinated, these muscles are transferred to as proximal a position as possible and sutured to the biceps muscle with no. 5 nonabsorbable sutures. The biceps is pulled distally and placed under tension while these muscles are sutured to it. This step is especially important if the prosthesis has been shortened, because it restores the length–tension relation of the biceps muscle. The elbow is kept in 60 degrees of flexion and fully supinated for the remainder of the procedure.

- The origin of the flexor–pronator forearm muscles also is transferred as far proximal as possible and sutured to the medial border of the biceps and triceps muscles.

- At this time, for postoperative analgesia, an epidural catheter can be threaded proximally along the median nerve, deep to the vascular sheath, to a level where it can bathe the entire brachial plexus with bupivicaine. A drain is also placed at this time.

- The remaining muscles, usually the biceps–brachialis muscles and triceps muscles, are sutured to each other to close over the entire prosthesis and neurovascular structures (TECH FIG 4).

- Sometimes, depending on the amount of soft tissue that is resected with the neoplasm, it is useful to shorten the prosthesis an additional 2 to 3 cm to facilitate soft tissue coverage. The biceps requires retensioning with sutures if this situation arises. Likewise, proximal transfer (ie, tensioning) of the brachioradialis and forearm flexor origins (ie, flexorplasty) is beneficial for restoring elbow flexion power.
**POSTOPERATIVE CARE**

- Edema control is essential in the early postoperative period. Patients are covered from hand to shoulder with a bulky dressing and a splint that maintains the elbow in 60 degrees of flexion. Elastic bandages are applied for light compression. The extremity is elevated and the patient remains primarily at bed rest for 3 to 4 days. Drains and the perineural catheter are removed at this time. The dressings are changed approximately 4 days postoperatively, and the splint is reapplied to maintain the elbow in 60 degrees of flexion.

- The extremity is kept in a splint for a total of 6 weeks to allow for sufficient muscle healing and scarring. Elbow motion is prohibited for 6 weeks.

- Immediately after surgery, active and passive range of motion of the wrist, hand, and digits, along with hand strengthening, is initiated and continued for 6 weeks while the arm is in the splint. Hand and wrist strengthening is continued throughout the entire rehabilitation process.

- At 6 weeks, the patient is placed in a hinged elbow brace and permitted active, active assisted, and passive range of motion from 30 degrees of flexion to 130 degrees of flexion. The patient is not permitted to extend the elbow for the next 6 weeks past approximately 30 degrees of flexion. At 12 weeks after surgery, the brace is adjusted to allow full motion of the elbow. Strengthening of the elbow is initiated at this time, with a 2-pound weight limit. The brace is worn for 6 more weeks, usually until approximately week 18. The patient can wear a sling after week 18 when necessary for comfort. At week 18, resistance strengthening can be increased to a 3-pound weight limit if the patient is now able to handle 2 pounds. At 6 months after surgery, the weight limit for resistance strengthening is increased to 10 pounds. Patients are advised not to lift more than 10 pounds with the extremity.

**OUTCOMES**

- **Oncologic results:** Local recurrence is less than 5%. In our series of 16 patients, there were no local recurrences.

- **Prosthetic survival:** In our small series of 16 patients, there were no instances of prosthetic loosening (FIG 3).

- **Function:** All patients are pain free and have stable elbows. Patients do not require a brace. Elbow, wrist, and hand function are virtually normal. All patients could flex their elbows up to 110 to 130 degrees. No patients lacked 10 to 30 degrees of terminal extension. All patients could carry out activities of daily living. The Musculoskeletal Tumor Society score ranged from 24 to 27 of 30 possible points (80% to 90%). The main restrictions are in recreational activities.

activities. Most patients can flex their elbows against 10 pounds of resistance.

COMPlications

- Transient nerve palsies (over 10%; 1 out of 16 patients); resolved within 6 months
- Skin necrosis and wound infections (over 10%; 1 out of 16 patients); resolved with debridement and closure
- Aseptic loosening (0 out of 16 patients)
- Local recurrence (0 out of 16 patients)
- In one instance the axle broke and was replaced.

REFERENCES

BACKGROUND

The humerus is a common site of metastatic bone disease requiring surgery. A metastasis at that site, especially when it involves the dominant extremity, has an immediate and profound impact on the affected individual’s ability to perform activities of daily living. The quality of surgery, therefore, is an important factor in restoring vital function.

A detailed preoperative clinical and imaging evaluation is mandatory for defining the morphologic characteristics of the lesion and, in turn, establishing the indications for surgical intervention, as well as distinguishing between lesions that can be managed with curettage and cemented fixation and those that require resection with endoprosthetic reconstruction.2,3,5,6

Unlike primary sarcomas of the humerus, metastatic tumors usually have a small soft tissue component, even in the presence of extensive bone destruction. This characteristic allows resection of bony elements only, permitting sparing of the extracortical structures, such as the joint capsule, overlying muscles, and muscle attachments, and affords the opportunity to use them to reconstruct and preserve function (FIG 1A,B). To this end, exposure of the proximal humerus is done by splitting the deltoid muscle rather using the deltopectoral interval, as is done in the case of a primary sarcoma of bone, which necessitates en bloc resection of the deltoid muscle with the tumor. Moreover, a few centimeters of upper limb shortening following resection of bone segment has minimal impact on function, because a slight difference in positioning of that extremity in space can easily compensate for such limb-length discrepancy.

In contrast, a similar discrepancy in the lower extremities, which require almost equal length for normal gait, would result in an inevitable limp, the extent of which would be proportional to the shortening of the operated extremity.2

Because of different anatomic and surgical considerations, surgeries around the proximal humerus (type I), humeral diaphysis (type II), and distal humerus (type III) are discussed separately (FIG 2).1

ANATOMY

Proximal Humerus: Type I Metastasis

The proximal humerus is covered anteriorly and laterally by the deltoid muscle.

The joint capsule encircles the humeral head and attaches to the base of the anatomic neck.

The proximal humerus is the attachment site for the rotator cuff muscles. The long head of the biceps muscle crosses the anterior aspect within the bicipital groove.

Humeral Diaphysis: Type II Metastasis

The upper half is occupied by muscle insertions:

- Medial aspect: teres major, latissimus dorsi, coracobrachialis
- Lateral aspect: pectoralis major, deltoid
- The radial nerve curves at the back from medial to lateral at the mid-arm level.
- The lower half is occupied by muscle origins:
  - Medial aspect: Brachialis
  - Lateral aspect: Brachioradialis
  - Neurovascular bundle along its medial aspect

Distal Humerus: Type III Metastasis

The neurovascular bundle lies along its medial aspect between the biceps and brachialis muscles.

- The radial nerve lies along its lateral aspect between the brachialis and brachioradialis muscles.

INDICATIONS

- Pathological fracture
- Impending pathological fracture
- Intractable pain associated with locally progressive disease that has shown inadequate response to narcotics and preoperative radiation therapy
- Solitary bone metastasis in selected patients

IMAGING AND OTHER STAGING STUDIES

Plain radiographs of the entire humerus are mandatory to rule out synchronous metastases that may change the extent and technique of surgery. A CT scan of the lesion will clearly define the extents of bone destruction and soft tissue component. Total body bone scintigraphy is done to detect synchronous metastases elsewhere in the skeleton. At the conclusion of imaging, the surgeon should be able to answer the following questions:

- Are there additional humeral metastases and, if there are, can they be managed by nonoperative techniques or do they require surgery?
- Are there additional skeletal metastases and, if there are, can they be managed by nonoperative techniques or do they require surgery?
- What is the appropriate surgery? As a rule, the tumor curettage and cemented fixation approach is used for lesions in which the remaining cortices allow containment of the fixation device; otherwise, surgery involves resection of the affected bone segment with prosthetic reconstruction.
Chapter 12  SURGICAL MANAGEMENT OF METASTATIC BONE DISEASE: HUMERAL LESIONS

FIG 1 • A. Primary bone sarcomas usually have considerable extension into the soft tissues. Resection of such tumors at the proximal humerus would require en bloc removal of the overlying deltoid muscle, rotator cuff tendons, and the joint capsule. 
B. Bone metastases, however, usually present with less soft tissue involvement, and their resection involves removal of bony elements with only a thin layer of surrounding soft tissues.

FIG 2 • A,B. Type I humeral metastasis extending across the anatomic neck to the humeral head. C,D. Type II humeral metastasis involving the humeral diaphysis between the anatomic neck and the supracondylar ridges of the humerus. E,F. Type III humeral metastasis extending to the humeral condyles below the supracondylar ridges. (From Bickels J, Kollender Y, Wittig JC, et al. Function after resection of numeral metastases. Analysis of 59 consecutive patients. Clin Orthop Relat Res 2005;437:201–208, with permission.)
TYPE I AND II METASTASES

Position and Incision
- The patient is placed in a semilateral position, and an anterior utilitarian shoulder girdle incision is made. It begins at the junction of the inner and middle thirds of the clavicle and continues over the coracoid process, along the deltopectoral groove, and down the arm over the medial border of the biceps muscle (TECH FIG 1A,B).

Exposure
- The deltoid muscle is divided longitudinally to expose the humeral head and the proximal third of the humeral diaphysis. Exposure of the remaining diaphysis is achieved by similarly dividing the brachialis muscle. Electrocautery and rasps are used to detach and reflect the periosteum and muscle attachments from the underlying cortex (TECH FIG 1C,D).

Tumor Removal
- Type I metastasis
  - Using electrocautery, the rotator cuff tendons are detached from the humerus, the long head of the biceps is cut at its insertion site around the glenoid, and the joint capsule is opened. Osteotomy is carried out at the required level below the surgical neck, 1 to 2 cm below the distal margin of the tumor, and the proximal humerus can now be removed (TECH FIG 2).

**TECH FIG 1 • A,B.** The utilitarian shoulder incision is used for exposure of type I and II metastases. It begins at the junction of the inner and middle thirds of the clavicle and continues over the coracoid process, along the deltopectoral groove, and down the arm over the medial border of the biceps muscle up to the distal arm, if required. **C,D.** The deltoid and brachialis muscles are divided longitudinally to expose the humeral head and humeral diaphysis. The periosteum is divided similarly and reflected with muscle to expose the underlying cortex.
Chapter 12  SURGICAL MANAGEMENT OF METASTATIC BONE DISEASE: HUMERAL LESIONS 1819

TECHNIQUES

TECH FIG 2 • A–C. Resection of the type I metastatic renal cell carcinoma seen in the plain radiograph in Figure 1C is executed by detaching the rotator cuff tendons and the long head of the biceps and opening the joint capsule. An osteotomy is performed and the proximal humeral segment is removed. D. Surgical specimen.

■ Type II metastasis
- A longitudinal cortical window with oval edges is made just above the lesion (TECH FIG 3A). Gross tumor is removed with hand curettes (TECH FIG 3B,C). Curettage should be meticulous and leave only microscopic disease in the tumor cavity. It is followed by high-speed burr drilling of walls of the tumor cavity (TECH FIG 3D–F). Occasionally, the cortices of the involved segment are completely destroyed, leaving no option but an intercalary resection of the affected segment. This is achieved by an osteotomy 1 to 2 cm above and below the segment (TECH FIG 3G–I).

Soft Tissue Reconstruction and Wound Closure
- Type I metastasis
  - The rotator cuff tendons are attached to the prosthetic head using 3-mm Dacron tapes (Deknatel, Falls River, MA) or no. 5 Ethibond sutures (Ethicon, Somerville, NJ; TECH FIG 6). The pectoralis major, teres major, latissimus dorsi, and coracobrachialis muscles are similarly attached. Using the same technique, the prosthetic head also is secured to the drill holes within the bony elements around the shoulder joint, acromion, clavicle, and glenoid. The second, overlying muscular layer includes the deltoid and brachialis muscles, which are sutured to cover the implant.

TYPE III METASTASES
- Type III metastases extend to the humeral condyles below the supracondylar ridges. In most of these cases, the extent of bone destruction allows tumor curettage and reconstruction with cemented hardware (the technique is described in the following section). Rarely will extensive destruction of the distal humerus necessitate formal resection with endoprosthetic reconstruction.
A longitudinal cortical window with oval edges is made just above the lesion. Gross tumor is removed with hand curettes. Curettage should be meticulous and should leave only microscopic disease in the tumor cavity. Curettage is followed by high-speed burr drilling of walls of the tumor cavity. Tumor cavity following curettage and burr drilling. Plain radiograph of type II thyroid carcinoma metastases. The extent of cortical destruction may does not allow curettage and burr drilling and so intercalary resection of the affected segment is indicated. Intercalary resection is achieved by proximal and distal osteotomies 1 to 2 cm above and below the tumor margin.
Position and Exposure

- The patient is placed supine on the operating table with the ipsilateral arm lying across the chest. A slightly curved incision is made on the lateral aspect of the arm over the supracondylar ridge of the elbow (TECH FIG 7A).
- The distal humerus is exposed using the plane between the brachioradialis and triceps muscles. The brachioradialis is reflected anteriorly and the triceps posteriorly. Further posterior reflection of the anconeus muscle combined with detachment and anterior reflection of the common extensor origin exposes the radial head (TECH FIG 7B).

Tumor Removal and Mechanical Reconstruction

- A longitudinal cortical window with oval edges is made just above the lesion. Gross tumor is removed with hand curettes (TECH FIG 8A), and this is followed by high-speed burr drilling (TECH FIG 8B).
- An intramedullary rod is introduced through the tumor cavity, which is then filled with cement. A reconstruction plate along the lateral supracondylar ridge is used to reinforce the reconstruction (TECH FIG 8C).

TECH FIG 4 • Intraoperative photograph (A) and plain radiograph (B) showing a proximal humeral tumor prosthesis used for reconstruction after resection of a type I metastasis.

TECH FIG 5 • A. An intramedullary nail is introduced. B. After proper position and length are verified, the nail is partially pulled back, and the entire tumor cavity is filled with cement. The nail is then pushed back into the medullary canal and fixed with interlocking screws. Intraoperative photograph (C) and plain radiograph (continued)
TECH FIG 5 • (continued) (D) showing side plate reinforcement of a cemented intramedullary humeral nail. Plain radiograph (E) and intraoperative photographs (F,G) showing side plate reinforcement of a cemented intramedullary humeral nail following intercalary resection of a type II metastasis. The remaining bone defect is filled with cement.

TECH FIG 6 • 3-mm Dacron tapes (A) or no. 5 Ethibond sutures (B) are used for securing the prosthetic head to the neighboring acromion, clavicle, and glenoid and for reattachment of the rotator cuff tendons. C. Rotator cuff tendons are sutured to the prosthetic head.
TECH FIG 7 • A. To expose a lesion at the distal humerus, the patient is placed supine on the operating table with the ipsilateral arm lying across the chest. A slightly curved incision is made on the lateral aspect of the arm over the supracondylar ridge of the elbow. B. The distal humerus and radial head are exposed using the plane between the brachioradialis and triceps muscles.

TECH FIG 8 • A. Gross tumor is removed with hand curettes. B. Curettage is followed by high-speed burr drilling. C. A cemented intramedullary rod that is reinforced by a reconstruction plate along the supracondylar ridge is used for reconstruction.
POSTOPERATIVE CARE

Type I and II Metastases
- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. If endoprosthetic reconstruction was done, the shoulder is immobilized in a sling for 3 weeks. During that time, the rehabilitation program emphasizes range of motion (ROM) of the elbow, wrist, and fingers with gravity assistance. Gradual passive and active ROM of the shoulder is then started, with emphasis on forward flexion, abduction, and shrugging.
- If tumor curettage has been carried out, ROM exercises should be practiced without delay. Once the wound has healed, usually 3 to 4 weeks after surgery, patients are referred to adjuvant radiation therapy. Radiation therapy usually is not required in patients who have undergone proximal humerus resection with endoprosthetic reconstruction.

Type III Metastases
- The wound is closed over suction drains. Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.
- Passive and active ROM exercises of the elbow joint are initiated when the suction drains are removed.
- Once the wound has healed, usually 3 to 4 weeks after surgery, the patient is referred to adjuvant radiation therapy. Radiation therapy usually is not required, however, for patients who have undergone distal humerus resection with endoprosthetic reconstruction.

OUTCOMES
- Most patients who undergo resection of a humeral metastasis experience immediate relief of their metastasis-related pain. Patients who had a type II metastasis and who have undergone either curettage or intercalary resection have better ROMs and superior functional outcome than those who underwent proximal or distal humeral resection with endoprosthetic reconstruction.

Bickels et al.2 reported that overall total function in their 56 patients (95%) who had undergone resection of a humeral metastasis was over 68% of full normal upper extremity function, which is the mean functional outcome score after reconstruction of the upper extremity.4

COMPLICATIONS
- Thromboembolic complications, deep wound infections, and prosthetic loosening (rare)
- Proximal humeral prosthetic dislocation, from poor securing to the adjacent bones and inadequate soft tissue coverage
- Decreased ROM around the shoulder, due to poor attachment of the rotator cuff tendons to the prosthesis
- Decreased elbow ROM after surgery around distal humerus lesions
- Local tumor recurrence of less than 5% if adjuvant tumor removal was done adequately and adjuvant radiation therapy was administered.

REFERENCES
BACKGROUND

- The axilla is a common site for primary soft tissue sarcomas as well as for metastatic disease that involves the axillary lymph nodes, such as advanced breast cancer or melanoma.
- Sarcomas typically arise from the muscles defining the axillary space (FIG 1). Occasionally, however, they may arise directly from the brachial plexus or axillary vessels (eg, malignant peripheral nerve sheath tumors, neurosarcoma, leiomyosarcoma). Several types of malignant tumors may involve the axillary space and may require surgical resection. Primary sarcomas occur within the muscles (ie, the pectoralis major, latissimus dorsi, teres major, and subscapularis muscles) that make up the borders of the axillary space. Rarely do they develop within the axillary fat itself. More commonly, large metastatic deposits to the regional lymph nodes create large, matted masses that may require resection. The most common of these are metastatic melanoma and recurrent breast carcinoma. In addition, there are primary tumors that arise from the brachial plexus, either the nerves or the vessels. These include leiomyosarcomas of the axillary vein and neurofibrosarcomas of the adjacent nerves.
- Small masses may be clinically silent, but large masses inevitably will result in significant pain or loss of function due to involvement of the brachial plexus.
- Venous occlusion may be seen in neglected, massive tumors and is a harbinger of loss of limb and possibly even of life due to gangrene.
- Historically, surgical management of tumors in this location consisted of forequarter amputation; advances in radiographic imaging, adjuvant therapies, and surgical techniques have greatly improved our ability to perform limb-sparing resections in this location. The key to adequate and safe surgical resection of axillary tumors is the complete visualization and mobilization of the infracavicular portion of the brachial plexus and the axillary artery and vein and the cords that surround them. In general, imaging studies of the axillary space are not reliable for determining vascular or nerve sheath involvement. Multiple imaging studies are required, but the ultimate decision to proceed with a limb-sparing surgery is based on the intraoperative findings at the time of exploration.
- Axillary tumors extending along the chest wall often can be elevated off the underlying ribs; however, tumor extension into the intercostal spaces may require thoracotomy and rib resection to ensure adequate margins.

ANATOMY

- The axilla is a pyramid-shaped space between the chest wall and the arm defined by its surrounding muscles; it appears triangular when seen from either the coronal or axial views.
- The superior apex of the pyramid is formed by the junction of the clavicle and the first rib, approximately 1 to 2 cm medial to the coracoid process.
- The muscular boundaries of the axilla consist of the pectoralis major muscle anteriorly; the subscapularis, teres major, and latissimus dorsi muscles posteriorly; and the coracobrachialis, short head of the biceps, and triceps muscles laterally.
- Vital structures in the axilla include the major branches of the infracavicular portion of the brachial plexus and the axillary vessels. Any surgery in this region requires detailed knowledge of and familiarity with these structures.

Infracavicular brachial plexus

- The lateral, posterior, and medial cords of the infracavicular brachial plexus are found at the level of the pectoralis minor muscle, where they then give rise to five major branches: the median, ulnar, radial, musculocutaneous, and axillary nerves. The cords and branches run along the axillary vascular sheath as it passes through the axilla.
- The lateral cord gives rise to the musculocutaneous nerve, which travels along the medial aspect of the conjoint tendon, where it innervates the coracobrachialis and short head of the biceps. This nerve is the first to be identified during the exploration, because it is located in the superficial axillary fat inferior to the coracoid process. The largest portion of the lateral cord combines with the medial cord to create the median nerve.
- The posterior cord gives rise to the axillary nerve, which travels deep in the space and passes inferior to the glenohumeral joint and subscapularis muscle, where it innervates the deltoid muscle. The main portion of the posterior cord becomes the radial nerve, which travels posterior to the sheath and exits the axillary space along with the axillary sheath.
- The medial cord gives rise to the ulnar nerve, which travels along the most medial aspect of the sheath and exits distally along with the sheath. Because of its medial position along the sheath, the ulnar nerve is the nerve most commonly involved by tumors arising inferior to the brachial plexus, which can present with symptoms of either weakness or neuropathic pain. The median nerve, formed by a combination of the lateral and medial cords, is found on the lateral aspect of the sheath and exits the inferior aspect of the axillary space along the sheath.

Axillary vessels

- The axillary artery and vein are the continuation of the subclavian vessels, changing name as they enter the apex of the axilla below the clavicle and first rib. These vessels run in a single sheath, surrounded by the cords of the brachial plexus. The vessels pass through the axillary space medial to the coracoid to the medial aspect along the humeral shaft. Distal to the teres major, the vessels are renamed the brachial vessels. Major vascular branches in the axillary space include the thoracoacromial artery (with its pectoral, deltoid, clavicular and acromial branches), the lateral thoracic artery, the subscapular artery, and the anterior and posterior humeral circumflex vessels.
Lymphatics
- A substantial amount of fat surrounds the vascular sheath as it runs through the axilla along with the lymphatics and lymph nodes. Major clusters of lymph nodes are found along the brachial and axillary vessels, the lateral thoracic vessels (anterior axillary nodes), and the subscapular vessels (posterior axillary nodes). Axillary tumors may arise from lymph node metastases anywhere along the axillary vessels; the most common sites are nodes along the distal portion of the axillary vessels.

INDICATIONS
- Any mass in the axillary space should be considered for biopsy or resection given the propensity for malignant tumors to develop in the axilla and the predictability of neurogenic pain arising from continued tumor growth.
- Palpate radial and ulnar pulses and inspect for venous congestion or swelling. Consider venography to evaluate loss of venous drainage indicative of tumor involving the brachial plexus.
- Dimunition of arterial flow is a late sign indicative of potential loss of limb—consider forequarter amputation.
- Test sensation and strength of the axillary, radial, median, and ulnar nerves. Loss of nerve function typically is a very late finding indicative of major tumor involvement of the brachial plexus—consider forequarter amputation.

IMAGING AND OTHER STAGING STUDIES
- Three-dimensional imaging of the axillary space is important for accurate anatomic tumor localization and surgical planning. CT, MRI, angiography, and three-phase bone scans are used in the same manner as in other anatomic sites. In addition, we have found that venography (of the axillary and brachial veins) is essential to the evaluation of tumors of the axilla and brachial plexus.

Plain Radiography
- Careful inspection of posterior–anterior chest, anterior shoulder, and axillary view radiographs may reveal the presence of increased soft tissue density corresponding to an axillary mass.
- Bone involvement and the presence of calcifications in the soft tissues should be noted.

Computed Tomography and Magnetic Resonance Imaging
- Multiplanar MRI is extremely helpful in visualizing the anatomic contents of the axillary space and defining the anatomic extent of the tumor (FIG 2A–C).
- Axial CT imaging, with administration of IV contrast, demonstrates the major vascular structures, outlines the major muscle planes, and can detect subtle matrix formation within the tumor. CT is most useful in evaluating the bony walls of the axilla, specifically the humerus, glenohumeral joint, and scapula (FIG 2D).
- Certain tumors, such as lipomas or hemangiomas, may have characteristic findings on T1- and T2-weighted MRI sequences suggestive of the proper histologic diagnosis. The presence or absence of lymphatic involvement should be noted, particularly in patients with a history of metastatic carcinoma.
- Although the brachial plexus may be very difficult to visualize, particularly when tumors distort or compress the surrounding fatty planes, the anatomic relationship of the nerve sheath to the vessels helps pinpoint their location.
- Although CT imaging of the lungs is routinely performed as part of patient staging, the chest wall should always be inspected carefully to rule out tumor involvement of the rib cage and pleural cavity.

Nuclear Imaging
- Positron emission tomography (PET) imaging, particularly when fused with MRI or CT imaging data, may significantly improve the ability to detect lymphatic spread of tumor in and around the axilla. Standardized uptake values (SUV) correlate...
with tumor metabolism and may help to distinguish between benign and malignant lesions.

**Angiography and Other Studies**

- **Angiography** remains a valuable method of imaging the axilla, particularly for preoperative planning, because tumors may significantly distort the regional vascular anatomy through mass effect as well as through angiogenesis (ie, formation of abnormal vessels feeding the tumor; **FIG 3**). Venography, either alone or in conjunction with angiography, can demonstrate venous compression from surrounding tumors. The axillary arterial wall is thick and rarely shows signs of occlusion, whereas the axillary vein is a thin-walled structure that is easily compressed and infiltrated by tumor. Therefore, occlusion is almost synonymous with involvement of the vascular sheath and brachial plexus. Venous occlusion, visualized as absent filling of the axillary vein, is characteristic of significant tumor involvement of the brachial plexus and warrants careful thought as to whether a limb-sparing procedure is possible. The triad of axillary venous occlusion, distal motor weakness, and neuropathic pain is a very reliable predictor of tumor infiltration of the brachial plexus sheath.

- **Infraclavicular brachial plexus and vascular exploration** is mandatory before resection is attempted. Tumor involvement of these structures usually indicates that a forequarter amputation is required.

**Biopsy**

- **Core needle biopsy** is the preferred method of diagnosis, because it minimizes risk of injury and contamination of the axillary contents. If a metastatic lesion is suspected, fine needle aspiration is the most appropriate means to identify carcinoma cells.

- **Large or superficial palpable masses** are amenable to needle biopsy in the clinic, whereas deep lesions are best approached with radiographic guidance using CT or ultrasound.

- **The biopsy tract should be positioned after consultation with the treating surgeon** to ensure proper location along the path of planned resection. The biopsy should be performed through the base of the axillary space, not through the pectoralis major muscle or near the vascular sheath. It can easily be performed under CT guidance. Deep-seated lesions near the chest wall also can be approached in this manner. Anterior lesions, on occasion, can be approached through

**FIG 2** - Imaging studies of the axillary space. **A.** T2-weighted MRI scan showing a large mass (arrow) occupying the axillary space. **B.** Coronal T2-weighted MRI scan showing a large tumor below the pectoralis major that fills the entire axillary space, from the clavicle to the lower end of the base of the pyramid that forms the axillary space. **C.** Axial MRI scan of a large fungating tumor from the axillary space. There are no muscle or skin components adjacent to the tumor, which protrudes anteriorly. **D.** CT scan of a primary bony sarcoma with a large extraosseous component that extends into the axilla. This finding is an excellent indication for the use of the anterior portion of the utilitarian incision for resections of large tumors of the proximal humerus. It demonstrates that the axillary space must be completely visualized and that the vessels must be mobilized.

**FIG 3** - Schematic representation of an axillary tumor with its relationship to the axillary sheath. **A.** The tumor does not involve the sheath but it displaces the artery, vein, and accompanying nerves. **B.** The tumor has invaded the axillary sheath, occluding the axillary vein. This is a significant finding on venography that almost always indicates vascular infiltration. **C.** Axillary venogram performed and shows complete occlusion of the axillary vein (red line). Collateral filling is seen around the mass. Obliteration of the vein almost always indicates infiltration of the infraclavicular plexus. **D.** Gross specimen following forequarter amputation showing tumor infiltration around the nerves and cords of the brachial plexus and surrounding the axillary artery and vein.
the lower portion of the pectoralis major muscle. The biopsy site must be removed in its entirety during resection of the tumor.

Open biopsy should be reserved for those patients in whom core needle biopsy was nondiagnostic or in those cases when additional samples of tumor are necessary for research purposes. Great care must be taken to avoid contamination of critical structures and otherwise uninvolved tissue planes. A small laterally placed incision, avoiding the pectoralis major muscle and the axillary sheath, is recommended.

Although small tumors are amenable to excisional biopsy, care must be taken to remove the entire pseudocapsule in the event that the tumor is found to be a sarcoma.

SURGICAL MANAGEMENT

Although many patients can safely undergo limb-sparing resections of the axillary space, extremely large or neglected tumors may present with significant involvement of the axillary vessels and brachial plexus.

Evidence of vascular involvement and, therefore, nerve sheath invasion should raise the question as to whether the patient is suitable for a limb-sparing resection; forequarter amputation may be necessary.

Proper placement of the biopsy tract is critical in limiting potential injury or contamination of the axillary space; large, poorly planned open biopsy tracts may necessitate forequarter amputation.

Adjuvant radiation to the axilla carries an increased risk of significant lymphedema, which can be functionally disabling, as well as potential wound problems.

Preoperative Planning

Careful review of preoperative imaging studies is necessary to formulate a surgical plan.

Extent of resection is determined by tumor size and stage and whether a palliative or curative option exists.

Consideration should be given to preoperative angiography or venography when vascular involvement is suspected on the basis of CT or MRI scans.

A double-lumen endotracheal tube should be used whenever preoperative imaging suggests significant rib involvement. Deflation of the underlying lung protects the lung during the rib resection.

Positioning

Positioning of the patient for axillary resection is determined by the size and anatomic extent of the tumor to be removed.

Most axillary tumors are best approached via an extensile anterior incision with the patient in the supine position. The patient is brought to the edge of the table, and a large padded bump is placed under the medial portion of the scapula to facilitate exposure. After prepping and draping the arm, axilla, and anterior shoulder girdle, the arm is placed over a padded Mayo stand, and the surgeon stands inside the axilla for the procedure. The surgical assistant is best placed superior to the arm to facilitate retraction.

Less commonly, the posterior or inferior portion of the axilla is involved, requiring access to the back of the axilla and shoulder girdle. When this is the case, the patient should be placed in the lateral decubitus position so that the entire shoulder girdle may be easily accessed. The arm is elevated over the patient’s head and supported by an assistant to permit access to the axilla. The surgeon should stand anterior to the patient, closest to the brachial plexus.

Approach

Anterior/medial utilitarian approach. The most commonly used approach for axillary resections is the common extensile approach to the shoulder girdle and arm, running along the deltopectoral groove. As the pectoralis major comprises the anterior anatomic boundary of the axilla, release of its broad tendon insertion into the humerus is vital to proper exposure of the axillary contents (FIG 4).
The traditional incision along the inferior boundary of the axilla offers a very limited view of the axillary contents and makes identification of the brachial plexus difficult. This incision is best used only for patients with tumor limited to the chest wall (inferior axillary resection) or posterior (latissimus) axilla.

A combination of the traditional axillary incision with the anterior extensile incision may be performed by extending the skin incision across the pectoralis muscle, meeting the anterior incision near the coracoid process (FIG 5). This is useful in the salvage of patients having attempted resections or open biopsies through the inferior axilla.

**FIG 5**  Surgical technique of exposure and resection of axillary tumors. A. The anterior portion of the utilitarian shoulder girdle incision is used. This is an extended deltopectoral incision, which may be curved in a posterior direction toward the axilla. The pectoralis major is then released 1 cm from its insertion onto the humerus. This is the first layer of axillary space musculature. B. Operative photograph showing the second muscle layer. The short head of the biceps and the pectoralis minor attach to the coracoid. The axillary contents with the vessels and nerves are not seen, because they are enclosed within the axillary fat and fascia. C. The musculocutaneous nerve is found 1 to 2 cm distal to the coracoid, below the insertion of the pectoralis minor and adjacent to the short head of the biceps. This nerve must be identified before the second layer of muscles is released. D,E. Resection bed following removal of the tumor of the axillary space. It is necessary to begin at the level of the clavicle and ligate all branches that pass distal and inferior to the tumor mass. Most tumors arise inferior to the neurovascular bundle.

**Axillary Exploration Through Anterior Approach**

- Identify landmarks.
  - Palpate and mark the bony landmarks: coracoid process, acromion, acromioclavicular joint.
  - Palpate the groove between the deltoid and pectoralis muscles.
- Incision
  - The skin incision should extend along the deltopectoral groove to the coracoid process and may curve into the axilla as needed. Open this interval, sparing or ligating the cephalic vein as necessary.
- Detachment of pectoralis major (TECH FIG 1)
  - Identify the pectoralis major insertion into the humeral shaft and release using the electrocautery approximately 1 cm from the bone to preserve enough insertion for later repair. After the pectoralis major is fully released from the humerus, retract the muscle medially over the anterior chest wall, preserving its vascular pedicles and exposing the serratus anterior.
  - Development of anterior axillary fascial plane
  - Develop the surgical plane along the clavpectoral fascia, which is a thick, well-defined layer that contains the axillary space and structures.
  - Release of conjoint tendon and pectoralis minor
  - Palpate the conjoint tendon insertion at the coracoid process and release. Protect the musculocutaneous nerve inserting into the muscle belly just distal to the tendon from the underlying brachial plexus by limiting distal retraction. Release of these muscles is key to exposing the vascular sheath and brachial plexus.
Neurologic exploration
- Identify the sheath of the brachial plexus and axillary vessels underneath the detached conjoint tendon. The musculocutaneous nerve comes around the lower border of the coracoid under the pectoralis minor muscle. The axillary nerve comes off deeper from the posterior cord and travels toward the shoulder joint. Both must be identified at this stage.

Vascular exploration
- Completely exposure and control the axillary vessels and brachial plexus proximally by opening the pedicle sheath and placing loops around the major structures; careful dissection is then used to mobilize these structures distally into the arm. Mobilization often is necessary to facilitate adequate exposure prior to tumor resection.

Resection of tumor
- All of the feeding branches entering into the mass are serially ligated and transected. Axillary fat is left around the tumor mass as the only true margin. The tumor is removed, tagged for orientation, and sent to pathology for margins and histologic evaluation.

Resection of Anterior Axillary and Chest Wall Tumors
- Tumors involving the pectoralis and serratus anterior can be resected safely following identification and mobilization of the critical neurovascular structures; these muscles may be elevated directly off the underlying chest wall.
- Resection of high-grade sarcomas may require sacrifice of one or more major branches of the brachial plexus to achieve an adequate oncologic margin. Loss of the median nerve results in the greatest loss of hand function.
- Chest wall involvement requires thoracotomy and resection of contiguous ribs; the underlying lung is deflated before opening the chest cavity to protect it.
- Intrathoracic extent of tumor may be determined by palpation of the pleural surface following thoracotomy; osteotomy of the ribs using a rib cutter under direct visualization permits en bloc removal of the involved chest wall.

Lymphatic involvement, frequently seen in patients with breast cancer extending into the axilla, requires meticulous dissection of the axillary and subclavian vessels proximally; sampling of lymph nodes is crucial in patients with carcinomas or melanoma.

Resection of Posterior Axillary Tumors
- Further exposure of the axilla is achieved by extending the vascular and neurologic exploration further down the arm, widening the area to reach posterior or distal tumors (TECH FIG 2).
- Identify the latissimus insertion into the humerus, which defines the posterior aspect of the axilla distal and posterior to the pectoralis insertion.
- Before performing tendon release, identify and protect the axillary nerve proximal to and the radial nerve distal to the tendon; both nerves serve to tether the brachial plexus and reduce the ability to retract the plexus.
- Tumor involvement of the latissimus may require sacrifice of one or both of these nerves.
- The latissimus muscle may be elevated off the chest wall as necessary for tumor resection.
- Chest wall involvement may require thoracotomy and resection of contiguous ribs; deflate the lung before opening the chest cavity to protect the underlying lung.
- Intrathoracic extent of tumor may be determined by palpation of the pleural surface following thoracotomy. Osteotomy of the ribs using a rib cutter under direct visualization permits en bloc removal of the involved chest wall.

Reconstruction Following Tumor Resection
- Repair and reconstruction of the axilla is necessary following tumor resection.
- Insertion of an epineural catheter into the sheath of the brachial plexus permits postoperative administration of local anesthetics such as bupivacaine (Marcaine) to minimize postoperative pain.
Reattachment of the conjoint tendon and pectoralis minor to the coracoid with the use of mattressed, nonabsorbable sutures covers the brachial plexus and axillary vessels.

Defects of the chest wall can be covered with local rotation flaps using the latissimus dorsi or pectoralis major muscle, which may be tenodesed to the subscapularis tendon as needed.

Careful wound closure over closed suction drains and placement of absorptive padding in the axilla reduce the risk of skin maceration and wound infection. Use of a sling or shoulder immobilizer permits early mobilization of the patient.

Functional deficits resulting from resection of portions of the brachial plexus may require delayed reconstruction after completion of adjuvant treatment.

**PEARLS AND PITFALLS**

**Preoperative angiogram and venogram**
- In addition to mapping out the course of the vessels, loss of flow through the brachial or axillary vein is a worrisome sign that tumor involves the brachial sheath. This often is the first sign of an unresectable tumor (FIG 6) for which forequarter amputation should be considered.

**Axillary incision**
- The axillary incision is not easily extended and severely restricts the ability to dissect out the neurovascular bundle. This incision is rarely indicated.

**Pectoralis major**
- Detachment of the humeral insertion is key to opening up the entire axilla and permits exploration of all important structures. It is not necessary to reattach the pectoralis to its insertion; rotation of this muscle is valuable for reconstruction of defects around the shoulder.

**Musculocutaneous nerve**
- Injury due to over-retraction of the conjoint tendon may occur, leading to loss of elbow flexion and resulting disability. This may be unavoidable for tumors involving the conjoint tendon.

**FIG 6** • Unresectable sarcoma of the axilla. A. Multiple recurrences with a large soft tissue mass. B. Operative view through the anterior incision showing a large tumor surrounding the axillary sheath.
POSTOPERATIVE CARE

- Postoperatively, a sling or shoulder immobilizer is applied to support the arm. Closed suction drains are removed after output slows.
- Patients are mobilized on postoperative day 1, from bed to chair. Ambulation is begun as tolerated to improve pulmonary function.
- A sling is used until the skin wound is sufficiently healed.
- Early shoulder motion with assistance is started as soon as the wound permits.
- Aggressive wrapping of the arm and use of custom-fitted compression gloves is started if there is evidence of lymphedema.

OUTCOMES

- Functional outcome is determined by the amount of muscle resection and loss of particular nerves.
- Loss of shoulder motion results in mild disability, which is easily compensated for by use of the other arm for overhead activities.

COMPLICATIONS

- Although uncommon, the complication most often seen following axillary resection is the accumulation of third-space fluid with secondary wound problems. Previous radiation therapy increases this probability. Use of suction drains and compressive dressings helps mitigate this complication.
- Chronic pain may occur following nerve resection, especially after radiation. Use of nerve sheath catheters with postoperative infusion of local anesthetics may reduce the incidence of neuropathic pain.
- Lymphedema may result in significant disability and chronic pain; early aggressive treatment may lessen the severity or duration of swelling. The risk is greatest following surgery and radiation therapy.
- Infections and flap necrosis following axillary tumor resections rarely occur, because of the substantial network of subcutaneous blood vessels perfusing the shoulder girdle.

REFERENCES

BACKGROUND
Forequarter amputation (interscapulothoracic amputation) entails en bloc removal of the upper extremity together with the scapula and the lateral aspect of the clavicle. This mutilating amputation of the upper extremity traditionally was done for high-grade sarcomas around the proximal humerus and scapula (FIG 1). Tumor response to chemotherapy and radiation therapy and the option of endoprosthetic reconstruction have made these procedures rare, and limb-sparing resections are safe alternatives in 90% to 95% of these cases.

ANATOMY
The upper extremity and scapula are attached to the upper torso and chest wall by soft tissue elements (ie, the rhomboid, levator scapulae, trapezius, pectoralis major and minor, latissimus dorsi, teres major, and serratus anterior muscles) and a single bone (ie, the clavicle). All of these must be transected to allow the performance of a forequarter amputation.

The axillary vessels and infraclavicular portion of the brachial plexus pass just inferiorly to the coracoid process, which is easily palpable, and lie below the deltopectoral fascia. These structures should be evaluated before surgery to determine the segment that can be safely transected and ligated, especially because large tumors may come close to the thoracic outlet.

Large tumors of the periscapular area may easily extend into the posterior triangle of the neck, the adjacent paraspinal muscles, and the underlying chest wall. Tumor extension into these anatomic sites must be evaluated carefully before surgery in case en bloc resection of a chest wall segment or a concomitant neck dissection is required.

INDICATIONS
Large soft tissue tumor around the proximal arm or axilla with neurovascular encasement and compromise and extension across the joint.
Large bone tumor (primary bone sarcoma or metastatic lesion) of the proximal humerus and scapula with and extensive soft tissue component and invasion into the shoulder joint and surrounding muscles.
Extensive locoregional tumor recurrence around the shoulder girdle.
Palliation of intractable pain or tumor fungation, associated with a rapidly enlarging lesion that has not responded to chemo- or radiation therapy (FIG 2).
Forequarter amputation usually is contraindicated when the tumor extends to the chest wall or to the posterior triangle of the neck and paraspinal muscles. This surgery can be considered in selected cases with no metastases, in which concomitant chest wall resection or neck dissection can achieve negative margins and patients can withstand the physiologic impact of these combined major surgeries.

IMAGING AND OTHER STAGING STUDIES
The combined use of CT and MRI allows the extent of bone and soft tissue tumor involvement to be determined and, thus, the potential size of the soft tissue margins to be estimated at the neck, paraspinal muscles, and chest wall (FIG 3).
Angiography is extremely helpful in locating the anatomic position of the axillary and brachial vessels, and in evaluating whether these structures are involved by tumor. Physical anomalies (eg, a duplicate axillary artery) occasionally are identified as well. Angiography also makes it possible to determine accurately the best level of ligation of the axillary vessels.
No imaging studies can distinguish precisely whether the brachial plexus is infiltrated by tumor or whether the vessels and plexus are simply displaced, and they provide only indirect evidence of tumor extension to the nerves. On the other hand, venography of the axillary veins is a simple and accurate method of determining brachial plexus involvement. A brachial venogram will show complete obstruction of the main axillary veins when tumor is infiltrating the brachial plexus, whereas it will show venous patency and displacement when a tumor is adjacent to, but not infiltrating, the plexus.

SURGICAL MANAGEMENT
Position
The patient is placed in a full lateral position and is secured to the operating table at the hips with tape. Alternatively, a VAC pack can be used to secure the torso. An axillary roll is placed under the axilla to allow full excursion of the chest, and a sponge-rubber pad is placed under the hip to prevent ischemic damage to the skin in this area. The skin is prepared in the usual manner, and the tumor-bearing extremity is draped free (FIG 4).

Text continues on page 1837
A. Forequarter amputation entails en bloc removal of the upper extremity together with the scapula and the lateral aspect of the clavicle. B. MRI scan showing an extremely large axillary sarcoma involving the shoulder joint. A forequarter amputation was performed. A forequarter amputation is less commonly performed today than in the past. The most common indications include large sarcomas or carcinomas of the axillary space with involvement of the bony shoulder girdle or tumor fungation through the axilla. Occasionally, metastatic breast carcinoma to the axilla requires forequarter amputation if there is brachial plexus involvement (as a palliative procedure).

A. Surgical illustration. B. Lymphoma of the shoulder girdle and brachial plexus with a non-union pathological fracture and no response to radiation therapy. This patient’s arm was essentially useless and was extremely painful. It is rare for lymphomas to fail to respond to adjuvant therapy. C. Clinical photograph demonstrating tumor fungation through the skin.
FIG 3 • A. Plain radiograph showing destruction of the proximal humerus and the shoulder joint, as well as a non-union fracture. B. Plain radiograph demonstrating very large soft tissue mass in the axillary region caused by extraosseous growth of a Ewing sarcoma. C. CT scan showing a large mass protruding into the axillary space with probable involvement of the brachial plexus. D. Coronal MRI scan of a 63-year-old woman who presented with a fungating sarcoma of the axilla with extension to the proximal arm and scapula. The neurovascular bundle was encased and compressed by the tumor, and the patient had overt edema of the upper extremity and compromised radial and median nerve functions. E. CT scan demonstrating a large Ewing sarcoma. F. MRI scan showing the tumor protruding through the skin, fungating from the axillary area and deep, near the serratus anterior chest wall. G. Axillary venography showing that the axillary vein is almost completely thrombosed from compression by surrounding tumor. This appearance has proven to be an extremely reliable prognostic finding of brachial plexus involvement. If axillary venography shows axillary vein obstruction, a forequarter amputation almost is always required at the time of exploratory surgery.
The patient is placed in a full lateral position and is secured to the operating table at the hips with tape. Alternatively, a VAC pack can be used to secure the torso. An axillary roll is placed under the axilla to allow full excursion of the chest, and a sponge-rubber pad is placed under the hip to prevent ischemic damage to the skin in this area. The skin is prepared, and the tumor-bearing extremity is draped free.

Positioning of a 35-year-old woman with a recurrent sarcoma of the axilla. Note the scar from the previous surgery at the deltopectoral groove. Intraoperative photographs showing a locally recurrent osteosarcoma at the proximal arm and axilla in a 34-year-old patient. A 59-year-old woman with a locally recurrent malignant melanoma extensively involving the arm, axilla, and shoulder that grew rapidly despite chemotherapy, immunotherapy, and radiation. Anterior approach. The first structure transected is the pectoralis major muscle. Posterior approach. The incision starts proximal over the shoulder and extends distally along the axillary border of the scapula and curves toward the midline. A large subcutaneous (or fasciocutaneous) flap is developed. The pectoralis major muscle has been transected; this photograph demonstrates the pectoralis minor over the tumor. A large posterior fasciocutaneous flap following a forequarter amputation for a large fungating tumor of the anterior axillary area. Therefore, a large posterior fasciocutaneous flap has been raised using a component of skin from the posterior two-thirds of the arm. This is a common technique when the usual anterior flap is compromised. This extended posterior fasciocutaneous flap is extremely reliable and can be rotated to close large chest wall and anterior defects as well as the posterior triangle of the neck. Closure of the entire surgical defect. Note the flap has covered the large area extending to the midline anterior, to the base of the neck, and the adjacent chest wall. (A: Courtesy of Martin M. Malawer.)
Incision

- The anterior component of the incision starts over the clavicle about 2 cm lateral to the sternoclavicular joint. Caudally, the incision line is in or near the deltopectoral groove; superiorly, it crosses the tip of the acromion. These two lines meet below the axilla to include the skin-bearing axillary hair and hematoma that results from the biopsy (TECH FIG 1).

- The final shape of the flaps and position of the lines of incision will vary according to the individual tumor extent. Because of the excellent blood supply to the skin in this region, long anterior or posterior flaps generally survive even though they are closed under considerable tension.

**TECH FIG 1**

- **A** The anterior component of the incision starts over the clavicle about 2 cm lateral to the sternoclavicular joint. Caudally, the incision line is in or near the deltopectoral groove; superiorly, the incision line crosses the tip of the acromion. Intraoperative photographs showing the anterior (B) and posterior (C) arms of the incision. These two lines meet below the axilla to include the skin-bearing axillary hair. **D.** The anterior flap is elevated, exposing the clavicle, acromion, and the overlying origin of the pectoralis major muscle. **E.** The origin of the muscle is detached from the clavicle, and an osteotomy is performed. **F.** The underlying brachial plexus and subclavian vessels are identified and clamped.
tension. Occasionally, large tumors extend to the overlying skin and require en bloc resection with a substantial area of skin. This results in a wound defect that cannot be closed primarily and will require a skin graft or be left for a delayed wound closure.

- The anterior skin flap, which can be extended to the mid-sternum, usually is constructed first, with the surgeon standing in front of the patient. The surgeon then switches position to stand behind the patient and constructs the posterior flap to the medial border of the scapula.

### Removal of the Affected Limb and Scapula

- Anterior vascular exploration is performed by detaching the pectoralis major muscle from the clavicle. A clavicular osteotomy is performed at the proximal one-third junction, and the underlying brachial plexus and subclavian vessels are identified. A Statinski clamp can be placed high along the vessels, and surgery can then proceed as planned.

- The posterior approach is used to detach the scapula from the rhomboid, trapezius, levator scapulae, and latissimus dorsi muscles. The scapula is lifted from the chest wall by detaching the serratus anterior muscle from its inner plate and the latissimus dorsi at its lowest point. This exposes the posterior chest wall and allows the surgeon to place his or her hand into the axillary space to check for chest wall or intercostal muscle involvement, whereupon the planned amputation can proceed.

- If the chest wall is involved, a combined chest wall and forequarter amputation can be performed. An axillary incision is made to connect the anterior and posterior incisions. The entire forequarter is removed after ligation and transection of the brachial plexus and subclavian vessels (TECH FIG 2).

### Soft Tissue Reconstruction and Wound Closure

- The area is copiously irrigated. The large posterior flap is closed over the remaining chest wall defect (TECH FIG 3A,B). Marked redundancy of the skin may present an unacceptable cosmetic appearance, so every effort should be made to ensure that the skin flaps are carefully approximated.

- The mid-portion of the long posterior skin flap is approximated to the mid-portion of the anterior flap. Carrying out the closure in this way pleats the longer posterior skin flap and prevents unsightly folds of skin. A two-layered closure, first of superficial fascia and then of skin, is used. Generous suction drainage under the anterior and posterior skin flaps is secured (TECH FIG 3C,D). Suction drains are removed when serous drainage is minimal.

Illustration (C) and intraoperative photograph (D) showing split-thickness graft used to cover the chest wall in tumors with skin infiltration over a wide area.

**PEARLS AND PITFALLS**

| Preoperative | Detailed radiologic assessment of the soft tissue extent of the tumor, its vascular anatomy, and determination of neck and chest wall invasion. If the latter exists and amputation is feasible, make the necessary preparations for concomitant chest wall resection or neck dissection. |
| Intraoperative | Patient is placed in a full lateral position. Clavicular osteotomy and clamping of the subclavian vessels are done first.  
Intraoperative palpation of the chest wall to assess tumor extension.  
Trimming of the posterior flap to avoid redundancy and formation of skin folds.  
Bupivacaine (Marcaine) infusion through an epineural catheter in the nerve sheath in an effort to decrease postoperative pain and causalgia. |
| Postoperative | Assisted postoperative ambulation to avoid loss of balance. Early occupational therapy. |

**POSTOPERATIVE CARE AND REHABILITATION**

- Continuous suction usually is required for 5 to 7 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. Phantom pain (causalgia) is a major problem following high-level amputations. We use an epineural catheter placed into the axillary sheath at the time of surgery and infuse 0.25% bupivacaine for 3 to 5 days postoperatively. This decreases postoperative pain and may lessen late causalgia syndromes.
- Patients initially have difficulty in keeping their balance because of the acute weight inequality of their upper torso and tend to fall toward the contralateral side. This problem typically resolves itself after a few days of assisted walking.
- It is crucial to have an occupational therapist involved early in the postoperative period to teach the patient how to perform the activities of daily living with a single upper extremity. This is even more critical when the amputated extremity is the dominant one.
- A cosmetic prosthesis can be fitted on wound healing and resolution of wound edema, usually 4 to 6 weeks after surgery.

**OUTCOMES**

- Forequarter amputation is a mutilating procedure that has a profound aesthetic, psychological, and functional impact on patients. Furthermore, it is done for large and aggressive tumors that bear a high risk of metastatic dissemination. Most patients who undergo forequarter amputation gain local con-
Chapter 14  FOREQUARTER AMPUTATION

Pain relief and improved quality of life are pronounced in patients who have undergone palliative amputation to control intractable pain associated with a rapidly enlarging tumor that had not responded to chemo- and radiation therapy. Most patients who undergo forequarter amputation regain reasonable function and are able to perform most daily activities.

For some still undefined reason, phantom limb pain is less common and less disturbing than that associated with high amputation of the lower extremities.

COMPLICATIONS

- Flap ischemia, usually superficial and marginal because of the good blood supply of the shoulder girdle (FIG 5); it usually resolves spontaneously.
- Occasionally, full-thickness necrosis of the posterior flap. A clear demarcation line appears after 4 to 7 days, after which debridement of the necrotic segment and primary closure is carried out.
- Phantom limb pain
- Local tumor recurrence

REFERENCES

BACKGROUND
- Tumors of the upper extremity may cause extensive soft tissue and bone destruction and extend into the main neurovascular bundle. In those extreme situations, limb-sparing may not be feasible, and amputation is required to achieve wide margins of resection and local tumor control.
- Above-elbow amputations may be required for advanced soft tissue and bone sarcomas of the forearm and around the elbow (FIG 1A). Below-elbow amputations are performed for such tumors of the forearm and the hand (FIG 1B).
- Above- and below-elbow amputations rarely are done, because (1) the upper arm, elbow, and forearms are rare location for musculoskeletal tumors and (2) when tumors do occur at one of those sites, they are noticed in relatively early stages and in most cases are resectable. Furthermore, administration of preoperative chemotherapy and availability of isolated limb perfusion have made it possible to achieve control in most patients with a large tumor.
- Nonetheless, above- and below-elbow amputations retain a definitive role in the management of soft tissue and bone tumors of the upper extremity.

ANATOMY
- Above-elbow amputations can be metaphyseal (high), diaphyseal, or supracondylar.
- High above-elbow amputations are those proximal to the deltoid tuberosity. Patients who undergo amputation proximal for musculoskeletal tumors and (2) when tumors do occur at one of those sites, they are noticed in relatively early stages and in most cases are resectable. Furthermore, administration of preoperative chemotherapy and availability of isolated limb perfusion have made it possible to achieve control in most patients with a large tumor.
- Below-elbow amputations should preserve the maximal length of both radius and ulna. Although tumors of the hand are treated by a standard below-elbow amputation, performed through the distal third of the forearm, tumors of the distal forearm require a higher amputation and warrant special consideration. A minimum of 2.5 to 3 cm of bony stump, measured from the radial tuberosity, is required to preserve function. Additional length in a very short stump can be obtained by releasing the biceps tendon; adequate flexion of the stump will be provided by the brachialis muscle.

INDICATIONS
- Extensive soft tissue and bone tumor extension with no option for reconstruction and reasonable function following resection (FIG 2A–E)
- Local recurrence formerly was considered a primary indication for amputation, but the mere presence of a recurrent sarcoma no longer is an immediate indication for an amputation. Whether or not it is possible to resect the recurrent tumor without compromising the function of the extremity is the factor on which the decision to amputate is based (FIG 2F).
- Major vascular involvement
  - The neurovascular bundle within the arm is tightly integrated in a closed anatomic space. The cephalic vein usually provides sufficient collateral flow if the brachial or the axillary vein has to be sacrificed. However, although the tumor mass occasionally can be delicately dissected off the brachial artery, in most cases of vascular involvement the brachial artery is extensively encased and amputation is inevitable.
  - The compact nature of the vascular supply to the wrist makes involvement of the radial and ulnar arteries likely when a large tumor invades the volar aspect of the distal forearm. In such a case, the incidence of morbidity and failure associated with resection and reconstruction using a vascular graft of one of these vessels is prohibitively high.
- Major nerve involvement
  - In general, one nerve around the arm can be sacrificed, and a two-nerve deficit is tolerated. Sacrifice of the three major nerves leaves the patient with a functionless extremity that is better off amputated.
  - Techniques for nerve grafting for replacement of a section of the median, radial, or ulnar nerves have not yet developed to a point at which satisfactory function can be obtained.

IMAGING AND OTHER STAGING STUDIES
- Patients requiring above- or below-elbow amputations for a soft tissue or primary bone sarcoma must undergo complete staging to allow the surgeon to determine the level of amputation and extent of soft tissue resection needed. Complete staging allows determination of full tumor extent and, as a result, the site for skin incision, shape of the flaps, and site of osteotomy.
- The combined use of plain radiography, CT, and MRI is necessary to determine the proximal extent of the intraosseous and soft tissue components of the tumor. In general, the more proximal of the two levels of involvement (ie, bone or soft tissue) determines the level of amputation.
A. Above-elbow amputations are done for advanced soft tissue and bone sarcomas of the forearm. Skin incisions and osteotomy sites for metaphyseal (high), diaphyseal, and supracondylar above-elbow amputations.

B. Below-elbow amputations are done for advanced soft tissue and bone tumors of the forearm and hand. Skin incision and osteotomy site for below-elbow amputation. (Courtesy of Martin M. Malawer.)

FIG 2 • Clinical photograph (A) and plain radiograph (B) showing metastatic carcinoma of lung to the mid-ulna with extensive bone destruction and soft tissue extension, requiring above-elbow amputation to achieve local tumor control and palliate pain. Clinical photograph (C) and plain radiograph (D) showing high-grade sarcoma of the first metacarpus, requiring below-elbow amputation to achieve local tumor control. E. Extensive squamous cell carcinomatosis of the forearm. Above-elbow amputation was done. F. Recurrent high-grade sarcoma of the distal forearm. The recurrent disease is diffused, and wide resection would result in loss of neurovascular structures and all flexor tendons, and would end with an extensive soft tissue defect in a previously irradiated surgical field. Below-elbow amputation was done, therefore following the previously planned incision (outlined).
ABOVE- AND BELOW-ELBOW AMPUTATIONS

- The patient is supine with the ipsilateral shoulder slightly elevated. Standard anterior–posterior “fishmouth” flaps usually are used (TECH FIG 1A). However, medial–lateral flaps occasionally may be needed because of local tumor anatomy. Because of the excellent blood supply to the upper extremity, wound healing is rarely a problem, regardless of flap configuration. The skin and superficial fascia are divided perpendicular to the skin surface.

- Large blood vessels are ligated in continuity and then suture ligated. The nerves are handled delicately. They are pulled approximately 2 cm from their muscular bed, doubly ligated with nonabsorbable monofilament suture, and cut with a knife.

- Muscles are transected according to the flap design, and the humerus or the radius and ulna are cut at the appropriate location, as determined by the preoperative imaging studies (TECH FIG 1B,C). The radius and ulna are transected so that they are the same length.

- For optimal function and mobility of the stump, it is important for muscle groups to be positioned tightly and securely over the cut ends of the bones (TECH FIG 2A,B). Myodesis is reinforced by Dacron tapes, passed through drill-holes made in the cut end of the bone. Superficial fascia and skin are closed over closed suction drains (TECH FIG 2C,D). An epineural catheter, bolused with 0.25 J. bupivicane, is inserted into the nerve sheath (TECH FIG 2E).

TECH FIG 1 • A. Anterior–posterior “fishmouth” flaps are used. The skin and superficial fascia are divided perpendicular to the skin surface. B,C. Osteotomies are performed at the appropriate location, as determined by the preoperative imaging studies. B. Above-elbow amputation. C. Below-elbow amputation. The radius and ulna are transected at equal lengths. (Courtesy of Martin M. Malawer.)

</table>

POSTOPERATIVE CARE

- A rigid dressing is applied immediately postoperatively to decrease pain and edema and facilitate maturation of the stump (FIG 3). Care must be taken to protect the skin that directly overlies the bone.
- Stump edema rarely is a significant problem in the upper extremity, and prosthesis training should begin as soon as possible after surgery.
- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.
- Active and passive range-of-motion exercises around the shoulder and elbow (if it exists) are practiced as tolerated.

COMPLICATIONS

- Wound dehiscence
- Deep infection
- Loss of elbow motion (when above-elbow amputation is done)
- Phantom limb pain
BACKGROUND
- Conventionally, curettage or piecemeal excision has been the usual approach to vertebral tumors.
- These approaches have clear disadvantages, however, including high risk of tumor cell contamination to the surrounding structures and residual tumor tissue at the site due to difficulty in demarcating tumor from healthy tissue.
- These contribute to incomplete resection of the tumor as well as high local recurrence rates of the spinal malignant tumor.
- To reduce local recurrence and to increase survival, we have developed total en bloc spondylectomy (TES).10,11,14
- In this method, the entire vertebra or vertebrae containing the malignant tumor are resected, together with en bloc laminectomy, en bloc corpectomy, and bilateral pediculotomy using a T-saw through the posterior approach.9
- Using this technique, we are able to excise the tumor mass together with a wide or marginal margin.

ANATOMY
- The following tissues serve as barriers to spinal tumor progression: the anterior longitudinal ligament (ALL), the posterior longitudinal ligament (PLL), the periosteum abutting the spinal canal, the ligamentum flavum (LF), the periosteum of the lamina and spinous process, the interspinous ligament (ISL), the supraspinous ligament (SSL), the cartilaginous endplate, and the cartilaginous annulus fibrosus. However, both the PLL and the periosteum on the lateral side of the vertebral body are “weak” anatomic barriers. In contrast, the ALL, cartilaginous endplate, and annulus fibrosus are “strong” barriers. In the spine one vertebra could be regarded as a single oncologic compartment and the surrounding tissues as barriers to tumor spread (FIG 1).5

INDICATIONS
- Surgical indication for primary tumors
  - The surgical strategy for primary spinal tumors used at the authors’ institution is based on Enneking’s concept of musculoskeletal tumors5 (Table 1).
- Surgical indication for metastatic tumors
  - Surgical strategy for spinal metastases (Table 2) consists of three prognostic factors: (1) grade of malignancy; (2) visceral metastases; and (3) bone metastases.12
  - The extent of the spinal metastases is stratified using the surgical classification of spinal tumors (Table 3), and technically appropriate and feasible surgery is employed, such as en bloc spondylectomy, piecemeal thorough excision, curettage, or palliative surgery.

IMAGING AND OTHER STAGING STUDIES
- Plain radiography
- CT/MRI
- Bone scan
- Angiography and other studies
- Biopsy

SURGICAL MANAGEMENT
- The TES operation was designed to achieve complete tumor resection en bloc, including main and satellite microlesions in a vertebral compartment to avoid local recurrence.
- The primary candidates for TES are primary malignant tumor (stage 1, 2); aggressive benign tumor (stage 3); and isolated metastasis in a patient with long life expectancy (see Tables 1 and 2).
- From the viewpoint of tumor growth (see Surgical classification; Table 3), TES is recommended for types 3, 4, and 5 lesions; and relatively indicated for types 1, 2, and 6 lesions.
- Type 1 or 2 still can be a candidate for radiation therapy, chemotherapy, corpectomy, or hemivertebrectomy.
- TES is not recommended for type 7 lesions. Systemic treatment or hospice care may be the treatment choice for these lesions.10,11,13 However, the final decision can be made individually based on discussion among the patient and his or her family and doctors.

Preoperative Embolization
- Segmental arteries above and below the feeding artery, as well as the feeding artery itself, should be embolized preoperatively.
- This embolization technique dramatically reduces intraoperative bleeding without compromising spinal cord function.4,8,15

Positioning
- The patient is placed prone over the Relton-Hall four-poster frame for the posterior approach to avoid compression to the vena cava.

Approach
- The surgical approach is decided based on the degree of tumor development or affected spinal level.

Single Posterior Approach
- For TES above L4, a single posterior approach is preferred rather than a postero–anterior combined approach, as long as the tumor does not involve major vessels or segmental arteries.

Anteroposterior Double Approach
- In type 5 or 6 tumors that involve major vessels or segmental arteries, anterior dissection followed by posterior TES is indicated. Currently, a thoracoscopic or mini-open approach is preferred for anterior dissection.

Posteroanterior Double Approach
- Posterior laminectomy and stabilization followed by anterior en bloc corpectomy and placement of a vertebral prosthesis is indicated in spinal tumors at the level of L5 or L4 because of the technical challenge presented by the iliac wing and lumbosacral plexus nerves.

</table>
Exposure
- A straight vertical midline incision is made over the spinous processes and is extended three vertebrae above and below the involved segment(s).
- The paraspinal muscles are dissected from the spinous processes and the laminae, and then retracted laterally.
- If the patient underwent a posterior route biopsy, the tracts are carefully resected in a manner similar to that used in limb-salvaging procedures.
- After a careful dissection of the area around the facet joints, a large retractor, the articulated spinal retractor, which has a uniaxial joint in each limb and was designed for this surgery, is applied.
- By spreading the retractor and detaching the muscles around the facet joints, a wider exposure is then obtained.
- The operative field must be wide enough on both sides to allow dissection under the surface of the transverse processes.
- In the thoracic spine, the ribs on the affected level are transected 3 to 4 cm lateral to the costotransverse joint, and the pleura is bluntly separated from the vertebra (TECH FIG 1).
- To expose the superior articular process of the uppermost vertebra, the spinous and inferior articular processes of the neighboring vertebra are osteotomized and removed with dissection of the attached soft tissues, including the ligamentum flavum.

Introduction of the T-saw Guide
- To make an exit for the T-saw guide through the nerve root canal, the soft tissue attached to the inferior aspect of the pars interarticularis is dissected and removed, using utmost care so as not to damage the corresponding nerve root.
- A C-curved malleable T-saw guide is then introduced through the intervertebral foramen in a cephalocaudal direction.
- In this procedure, the tip of the T-saw guide should be introduced along the medial cortex of the lamina and the pedicle so as not to injure the spinal cord and the nerve root (TECH FIG 2).
- After passing the T-saw guide, its tip at the exit of the nerve root canal can be found beneath the inferior border of the pars interarticularis.
- A T-saw is passed through the hole in the wire guide and is clamped with a T-saw holder at each end.
- The T-saw guide is removed, and tension on the T-saw is maintained.

Cutting the Pedicles and En Bloc Laminectomy
- While tension is maintained, the T-saw is placed beneath the superior articular and transverse processes with a specially designed T-saw manipulator. With this procedure, the T-saw placed around the lamina is wrapped around the pedicle.
- With a reciprocating motion of the T-saw, the pedicles are cut, and then the whole posterior element of the spine (the spinous process, the superior and inferior articular processes, the transverse process, and the pedicle) is removed in one piece (TECH FIG 3).
- The cut surface of the pedicle is sealed with bone wax to reduce bleeding and to minimize contamination by tumor cells.1
To maintain stability after segmental resection of the anterior column, a temporary posterior instrumentation ("two above and two below" segmental fixation) is performed.

Blunt Dissection Around the Vertebral Body

- The spinal branch of the segmental artery, which runs along the nerve root, is ligated and divided. In the thoracic spine, the nerve root is cut on the side from which the affected vertebra is removed.
- The blunt dissection is done on both sides through the plane between the pleura (or the iliopsoas muscle) and the vertebral body (TECH FIG 4).
- Usually, the lateral aspect of the body is easily dissected with a curved vertebral spatula.
- Then the segmental artery should be dissected from the vertebral body.
- By continuing dissection of both lateral sides of the vertebral body anteriorly, the aorta is carefully dissected posteriorly from the anterior aspect of the vertebral body with a spatula and the surgeon’s fingers.
- When the surgeon’s fingertips meet with each other anterior to the vertebral body, a series of spatulas, starting from the smallest size, are inserted sequentially to extend the dissection.
- A pair of the largest spatulas is kept in the dissection site to prevent the surrounding tissues and organs from iatrogenic injury and to make the surgical field wide enough for the surgeon to manipulate the anterior column.

Dissection of the Spinal Cord and En Bloc Corpectomy

- Using a cord spatula, the spinal cord (dura mater) is mobilized from the surrounding venous plexus and the ligamentous tissue.
- T-saws are inserted at the proximal and distal cutting levels of the vertebral bodies after confirmation of the disc levels with needles. Recently, a diamond T-saw is now available for corpectomy.
- The teeth-cord protector, which has teeth on both edges to prevent the T-saw from slipping, is then applied.
- The anterior column of the vertebra is cut by the T-saw, together with the anterior and posterior longitudinal ligaments (TECH FIG 5).
- The freed anterior column is rotated around the spinal cord and removed carefully to avoid injury to the spinal cord.
- With this procedure, a complete anterior and posterior decompression of the spinal cord (circumspinal decompression) and total en bloc resection of the vertebral tumor are achieved.

Anterior Reconstruction and Posterior Instrumentation

- An anchor hole on the cut end of the remaining vertebra is made on each side to seat the graft. A vertebral spacer such as a titanium mesh cylinder cage with autograft, allograft, or cement (TECH FIG 6) is properly inserted to the anchor holes within the remaining healthy vertebrae.
- After checking the appropriate position of the vertebral spacer radiographically, the posterior instrumentation is adjusted to slightly compress the inserted vertebral spacer.
- By this "spinal shortening" procedure, the block cylinder is caught tightly and the anteroposterior 360-degree spinal reconstruction is completed. 2,7
- If two or three vertebrae are resected, it is recommended that the connector device be applied between the posterior rods and anterior spacer (artificial pedicle).

Chapter 16  TOTAL EN BLOC SPONDYLECTOMY 1853

POSTOPERATIVE CARE

- Suction drainage is used for 3 to 5 days after surgery.
- The patient is allowed to start walking within 1 week after surgery.
- The patient wears a thoracolumbosacral orthosis for 3 to 6 months until bony union is attained.

OUTCOMES

- From 1989 to 2003, 284 patients with spinal tumors (primary, 86 patients; metastasis, 198 patients) were surgically treated and followed for a minimum of 2 years.
- Total en bloc spondylectomy was performed in 33 of the 86 patients with a primary tumor; 17 patients with malignant tumors (3 osteosarcoma, 3 Ewing sarcoma, 3 plasmocytoma, 2 chondrosarcoma, and 1 case each of 6 other tumors) and 16 patients with aggressive benign tumors (4 patients with giant cell tumor, 3 patients with osteoblastoma, 3 patients with symptomatic hemangioma, and 1 case each of 6 other tumors).
- Five-year survival of the 17 patients with primary malignant spinal tumors (stages 1 and 2) who underwent TES was 67%, and that of the 16 patients with aggressive benign tumors (stages 2 and 3) was 100%.
- In the same periods, TES was performed in 64 of 198 patients with spinal metastases. Of the 64 cases with a metastatic tumor, the primary organs were as follows: kidney, 18 cases; breast, 15 cases; thyroid, 9 cases; lung, 4 cases; liver, 4 cases; and other carcinoma, 14 cases.
- Forty-three patients with the 2, 3, 4 points out of 64 patients who underwent TES resulted in 2-year survival of 66.6% and 5-year survival of 46.6%.

- Ninety-two of 97 patients (95%) had no tumor recurrence until death or last follow-up.
- Five of 97 patients (5%) had local recurrence; the mean length of the recurrence was 22.1 months after operation.
- In all five patients with local recurrence, the recurrence arose from residual tumor tissue.

COMPLICATIONS

- Excessive bleeding
- Injury of the major vessels during blunt dissection of the vertebral body
- Spinal cord injury
- Injury of lung or pleura
- Postoperative hematoma
- Liquorrhea
- Pleural effusion
- Chylothorax
- Instrumentation failure
- Infection, especially after preoperative radiation therapy

REFERENCES

BACKGROUND

- The pelvis is a relatively common anatomic location for metastatic and primary musculoskeletal tumors. Surgical resection is more challenging in the pelvis than in other locations because of the complex anatomy and the proximity to vital abdominal viscera and major blood vessels and nerves. Making decisions about surgical resectability of a tumor involves the assessment of possible osseous or neurovascular involvement, in addition to the possible involvement of adjacent viscera (ie, bowel, ureter, and bladder). Therefore, preoperative evaluation and extensive imaging are critical. Osseous resection and reconstruction usually are carried out adjacent to major nerves, beneath the iliac vessels, or adjacent to the bladder or bowel.

- Tumor surgery around the pelvis has the highest rate of complications, infections, and mechanical failure of all anatomic sites.

ANATOMY (FIG 1)

Pelvic Nerves

Sciatic Nerve
- The sciatic nerve arises from L4, L5, S1, S2, and S3. The nerve emerges from the pelvis through the greater sciatic notch inferior to the piriformis muscle and enters the thigh lateral to the ischial tuberosity. In 10% of patients, the sciatic nerve penetrates the substance of the piriformis muscle. The sciatic nerve is accompanied by the inferior gluteal artery.

- It is essential to protect the sciatic nerve early in most procedures. Inside the pelvis, the nerve should be identified distally at the greater sciatic notch. Proximally, it should be picked up below the psoas muscle. The sciatic nerve is formed at the junction of the lumbar sacral plexus where these two trunks come together.

- Great care must be taken as the nerve exits the pelvis at the level of the greater sciatic notch not to injure the the accompanying inferior and superior gluteal nerves and arteries, because these supply the abductors as well as the gluteus maximus muscle. The gluteus maximus muscle is essential for closure of most pelvic resections.

Femoral Nerve
- The femoral nerve arises from posterior divisions of the ventral rami of L2 and L3 and passes inferolaterally between the psoas and iliacus muscles. It passes over the superficial iliacus muscle to enter the proximal thigh underneath the inguinal ligament, just lateral to the superficial femoral artery.

- This nerve is almost always preserved during pelvic resections. It should be identified early during most procedures. The femoral nerve is identified in the space between the iliacus and psoas muscles as they exit the pelvis. The femoral nerve lies just below the fascia, bridging the interval between the two muscles, lateral to the femoral artery and vein.

<tbody>
<tr>
<td>The obturator nerve, formed from the anterior branches of L2, L3, and L4, is the largest nerve formed from anterior divisions of the lumbar plexus. The nerve descends thru the iliopectineus muscle and courses distally over the sacral ala into the lesser pelvis, lying lateral to the ureter and under the internal iliac vessels. It then traverses the obturator foramen into the medial thigh, under the superior pubic ramus, dividing into anterior and posterior branches.</td>

| This nerve is routinely transected during pelvic floor resections (type 3) due to its intimate proximity to the tumor. |

Pelvic Vessels

Aortic Bifurcation
- Descending the abdomen to the left of the vena cava, the aorta bifurcates at the level of L4 into common iliac vessels at the level of L4-L5. The common iliac bifurcates into internal and external iliac vessels at the level of S1, the ala sacralis. The level of these bifurcations may vary, especially if the vessels are pushed by a large adjacent tumor mass. |

- It is essential to identify two levels of bifurcations prior to any ligation: the aortic bifurcation and the common iliac bifurcation. Even the best surgeons have ligated the wrong vessels due to distorted anatomy. Such a misstep is especially possible with tumors that cross the midline. Preoperative evaluation with angiography is required for evaluation and preoperative to avert such an occurrence. |

Common Iliac Artery
- The common iliac artery must be identified early to correctly identify the aorta as well as the the internal iliac (hypogastric) artery. To the surgeon, the major anatomic features of the common iliac artery are as follows: |
  - No arterial branches arise from the artery (although the common iliac vein does have a major branch joining in, the iliolumbar vein) |
  - The bifurcation of the common iliac artery into the external and internal iliac arteries is at the exact level at which the ureter crosses on the adjacent peritoneal surface. The ureter is routinely identified at this location early in the retroperitoneal dissection. |

External Iliac Artery
- The external iliac artery contributes to the inferior epigastric artery and extends distally, as the superficial femoral artery,
into the femoral triangle, where it is a useful landmark in identifying neighboring structures.

**Internal Iliac Artery**
- The internal iliac (hypogastric) artery descends from the lumbosacral articulation to the greater sciatic notch and branches into several arteries. The internal iliac artery and vein often are difficult to identify or ligate. The internal iliac artery lies on top of its vein, which often is large and is easily injured. The hypogastric vessels are routinely ligated in performing modified hemipelvectomies as well as many pelvic resections.

**Anterior Branches**
- The obturator artery exits the pelvis via the obturator canal (beneath the superior pubic ramus).
- The inferior gluteal artery curves posteriorly between the first and second and third sacral nerves, then runs between the piriformis and coccygeus muscles or through the greater sciatic foramen into the gluteal region below the piriformis muscle.

**Posterior Branches**
- The iliolumbar artery ascends posterior to the obturator nerve and external iliac vessels to the medial border of the psoas. It then divides into the lumbar branch, to the psoas and quadratus lumborum muscles and to the spinal cord, and an iliac branch, to the iliac, gluteal, and abdominal musculature. The iliac branch often is ligated during surgery.
- The superior gluteal artery runs posteriorly between the lumbosacral trunk and first sacral nerve and leaves the pelvis through the greater sciatic foramen superior and posterior to the piriformis muscle. Great care must be taken to preserve the gluteal vessels and nerves when performing types 1 and 2 pelvic resections.

**Ureter**
- The ureter originates from the renal pelvis at the level of L1 and courses in the retroperitoneum to the medial surface of the psoas major muscle, crossed by spermatic or ovarian vessels. The ureter crosses from lateral to medial on the surface of the peritoneum at the level of the common iliac bifurcation. This is a good landmark to identify the ureter during the initial retroperitoneal dissection. The ureter then courses medially at the level of the sciatic notch to insert into the trigone of the bladder.

**Corona Mortis**
- The corona mortis is an anastomosis of the external iliac, inferior epigastric, and obturator vessels located in the retroperitoneal region approximately 3 cm from the symphysis pubis. Laceration during an ilioinguinal approach can lead to extensive bleeding. The retroperitoneal space between pubis and bladder is called the space of Retzius.

**Inguinal Canal**
- The anatomic confines of the inguinal canal are described as 4 cm from the deep inguinal ring to the subcutaneous ring. This “deep ring” is the “direct” inguinal space originating lateral to the epigastric vessels. Hesselbach’s triangle is the “indirect” hernia space originating medial to the epigastric vessels.
- The inguinal contents vary by gender:
  - In males, the spermatic cord contains the ductus deferens, testicular artery, pampiniform plexus, lymphatics, autonomic nerves, the ilioinguinal and genital branches of the genitofemoral nerve, the cremasteric artery and muscle, and the internal spermatic fascia.
  - In females, the inguinal contents include the round ligament and the ilioinguinal nerve.
- The anterior inguinal wall is formed by the aponeurosis of the external oblique and internal oblique (lateral) muscles.
- The posterior inguinal wall runs medial to lateral and is formed by the reflected inguinal ligament, the inguinal falc, and the transversalis fascia.
- The superior or cephalic inguinal wall is formed by arched fibers of the internal oblique muscle and the transverse muscle of the abdomen.
- The inferior or caudal inguinal wall is formed by the inguinal and lacunar ligaments.

**Boundaries**

**Sciatic Notch**
- The sciatic notch should be identified early in surgery, both internally and externally, to protect the sciatic nerve and gluteal pedicles.

**Osseous Boundaries**
- The superior cephalad margin of the pelvis is defined by the ilium and the rim of the great sciatic notch.

**Posterior Margin**
- The posterior margin of the pelvis is bounded by the piriformis muscle and the superior gluteal vessels and nerve. Posterior to the piriformis muscle, the internal pudendal vessels and nerve course medially off the sciatic nerve and the posterior femoral cutaneous nerve, anterior to the piriformis.
Inferior Margin
- The sacrospinous and sactrotuberous ligaments are released during type 1 and 2 pelvic resections.

INDICATIONS
Recurrent Benign Tumors
- Major pelvic resections rarely are performed for benign bony tumors. Occasionally, following multiple recurrence or when tumors are limited to either the superior or inferior pubic rami, pelvic resection is indicated.
- Such benign tumors include large osteochondromas or any osteochondroma associated with multiple hereditary exostosis, due to the high risk of secondary chondrosarcoma.
- Osteoblastoma occurring in the ilium or periacetabulum
- Giant cell tumors or aneurysmal bone cysts have a predilection for the superior pubic ramus and supra-acetabulum.

Primary Malignant Osseous Tumors
- Osteosarcoma
  - Five percent of all osteosarcomas occur in the pelvis. Partial pelvic resection or hemipelvectomy (amputation) is required, usually following induction chemotherapy.
- Ewing sarcoma
  - About 25% of all Ewing sarcomas occur in the pelvis. Surgical resection is required.
  - Radiation therapy remains controversial in treating pelvic Ewing sarcoma.
  - Resection should be performed only following induction chemotherapy.
- Chondrosarcoma
  - Chondrosarcomas are the most common primary malignant bony tumors of the pelvis.

Metastatic Adenocarcinoma: Breast, Prostate, Renal, Lung, Colon
- Metastatic adenocarcinoma most commonly involves iliac or periacetabular sites. Most metastatic tumors to the pelvis are treated adequately with radiation therapy.
- Occasionally, there may be significant acetabular destruction with an impending pathological fracture that requires surgical reconstruction.
- Renal cell carcinoma (hypernephroma) metastases are an exception. These metastases often require surgical removal, either by resection or by curettage and cryosurgery. Preoperative embolization always is required for these vascular tumors to avoid severe bleeding during surgery.

Soft Tissue Sarcomas
- Retroperitoneal soft tissue sarcomas are more common than intraperitoneal sarcomas and must be evaluated for gastrointestinal, genitourinary, vascular or peripheral nerve involvement.

IMAGING AND OTHER STAGING STUDIES
Plain Radiography
- Plain radiography (FIG 2) is of limited value in the assessment of pelvic girdle lesions. Images often are obscure and confusing.
- The pelvis, particularly the sacrum, is a difficult structure in which to recognize early bone lesions, and major bone lesions initially may be overlooked. For these reasons, there

FIG 2 • A. Plain radiographs revealing a large lytic lesion of the right periacetabular region. On the basis of this radiograph, it appears that the cortices are intact. B. AP plain radiograph of the pelvis, read as normal. C. Plain radiographs revealing a cartilage-forming lesion in the left ilium. On the basis of this study alone, it seems that this is an intraosseous lesion. Plain radiographs performed 24 hours after a CT-guided core needle biopsy of a sacral lesion (note the coil) (D) and after 6 weeks (E).
should be a low threshold for performing further imaging, especially for initial screening and the postoperative evaluation of reconstructions.

**CT and MRI**
- CT with intravenous contrast and three-dimensional reconstruction is the optimal technique for assessing the extent of bone involvement and destruction, the osseous anatomy, and the relation between the tumor and the major blood vessels of the pelvis (FIG 3). It is valuable for depicting any distortion of the pelvic anatomy, and aiding in the evaluation of the tumor to decide whether it is resectable. Chest CT is essential for staging purposes in evaluation for pulmonary metastases.
- MRI with contrast is critical for imaging soft tissue (ie, vessels, nerve, muscle) and osseous involvement. MRI is the optimal modality for imaging soft tissue and marrow involvement. It is attractive for assessment of osseous disease and sacral involvement, and may be helpful with the serial assessment of neoadjuvant (induction) therapy.

**Bone Scan**
- Three-phase bone scan is used to rule out systemic metastasis and to assess the focal osseous involvement and tumor vascularity in the initial flow phase. A decrease in vascularity after induction chemotherapy may indicate response to treatment.

**Angiography**
- Angiography is mandatory for determining the vascular anatomy that often is distorted by large pelvic tumors (FIG 4). It is essential to determine the level of the various bifurcations preoperatively and to rule out vascular involvement by the tumor. Embolization of the tumor blood supply before surgery is helpful in minimizing blood loss, especially with vascular tumors and tumors with sacral involvement.

**Venography**
- The pelvic veins always are much larger than their arterial counterparts. Preoperative venography is used to rule out tumor (mural) thrombi, a common finding in chondrosarcomas and osteosarcomas. Their presence may change the planned surgical approach.

**FDG-PET**
- Fluorine-18 2-fluoro-2-deoxy-D-glucose-positron emission tomography (FDG-PET) may be useful in assessing the “grade” of malignancy, evaluating response to neoadjuvant chemotherapy, and monitoring for local recurrence. Positron emission tomography (PET) combined with CT or MR is useful for “co-registered” imaging. PET CT scans are useful in early detection of small recurrences. It plays only a minimal role in preoperative planning in determining the extent of surgical resection.

**Biopsy**
- The purpose of biopsy is to yield a valid tumor diagnosis (benign vs. malignant), tumor grade (high vs. low grade), and tumor subtype (eg, leiomyosarcoma vs. malignant fibrous histiocytoma).
- Biopsies may be performed by either open or needle technique.
- Because open biopsy for pelvic tumors is an extensive procedure, needle biopsy—especially CT-guided needle biopsy—

---

**FIG 3** • A. CT showed extensive bone destruction and extension of the tumor to the pelvis and the right gluteal region. B. CT of the pelvis revealed a large destructive lesion of the sacrum. C. CT shows an extensive tumor on the medial aspect of the ilium with destruction of the inner table and extension of the pelvis. (A,B: Courtesy of Martin M. Malawer; C: Reprinted with permission from Cancer: Principles and Practice of Oncology, 5th ed. Philadelphia: Lippincott Williams & Wilkins, 1997;38.3:1789–1852.)

**FIG 4** • Preoperative angiography and embolization of the metastatic lesion shown in Fig 3A. (Courtesy of Martin M. Malawer.)
always is performed initially for both metastatic and primary pelvic tumors.

- Biopsy technique should follow established guidelines for incision placement within the line of eventual resection, minimize contamination of normal tissues (e.g., achieve adequate hemostasis at biopsy closure), and retrieve an adequate specimen for frozen section diagnosis. The biopsy should avoid the gluteal and groin areas, because they are potential sources for flaps for skin closure after anterior and posterior hemipelvectomy, if necessary.

- Use of the utilitarian surgical incision for open biopsy is recommended.

**Anatomic Considerations**

- Evaluation of the full anatomic extent of a pelvic tumor cannot be based on a single imaging modality. Combined data, gained from two or more imaging modalities, allow a realistic appreciation of the exact anatomic extent. Even when that information is available, however, the full extent of a pelvic tumor often is underestimated preoperatively.

- Review of any imaging study of the pelvis, because of the numerous anatomic details, must be performed very methodically. The authors review the structures from the back (mid-sacral region) and follow the pelvic girdle to the front (symphysis pubis), as described in the following paragraphs.

**Sacrum, Sacral Alae, and Sacroiliac Joint**

- Most patients who undergo extended hemipelvectomy, which necessitates transection of the sacrum through the ipsilateral neural foramina, regain function of the gastrointestinal and genitourinary tracts. Adding a contralateral compromise of the sacral nerve root will create a severe dysfunction. Tumors that penetrate the sacrum and cross the midline are considered unresectable because of the involvement of bilateral neural foramina.

- Bilateral neural foramina for the sciatic nerve extend laterally to the SI joint. Tumors in close proximity to a site in which a major nerve supply is usually located. Clinical evidence of femoral or sciatic nerve dysfunction usually means direct tumor involvement. In most cases the presence and extent of nerve involvement is established only at the time of surgery. Sacral plexus invasion by tumor has the same significance in terms of resectability as tumor invasion of the sacrum; bilateral involvement is an indicator of unresectability.

**Sciatic Notch and Nerve**

- The sciatic notch is the site of pelvic osteotomy in resections of the ilium or periacetabular region and in modified hemipelvectomy. CT establishes tumor extension to the sciatic notch, a tight space through which the sciatic nerve and superior gluteal vessels and nerve pass (FIG 6). The piriformis muscle, which divides the sciatic notch, is a key structure, because the sciatic nerve exits the pelvis underneath it and the superior gluteal artery exits the pelvis above it. The patency of the superior and inferior gluteal arteries, which supply the gluteal vasculature, is established by angiography. Adequate blood supply of the gluteal region is a major consideration in flap design, and the artery must be preserved in any pelvic resection, if oncologically feasible. The artery is located only a few millimeters from the peristeum of the sciatic notch roof, and it should be dissected carefully.

**Ilium**

- The inner aspect of the bone is covered by the iliacus muscle, which originates from the iliac crest. The iliacus is “pushed” by a growing bone sarcoma and serves as a major barrier to direct extension of tumor to the anatomic structures of the pelvis. Therefore, the iliacus can be used as a safe oncologic margin for resection. In contrast, metastatic carcinomas to the pelvis tend to invade the covering muscle layer in their early growth stage, and a surgical plane between the tumor and nearby structures cannot be easily defined (FIG 7).
Although any pelvic organ can be infiltrated by a tumor, structures that are anterior and posterior to the flare of the muscle (ie, sacral plexus, sciatic notch and nerve, femoral vessels and nerve, bladder, and prostate) are at greater risk for direct tumor extension.

**Extension to Pelvic Viscera**

- Direct involvement of a pelvic viscus by a pelvic girdle tumor is rare. Left-sided tumors are more likely to involve a component of the gastrointestinal tract because of its close proximity to the pelvic girdle at that point. A rectal tube is inserted preoperatively during any pelvic resection to facilitate identification of the rectum during dissection.

**Acetabulum and Hip Joint**

- Wide resection of any bone tumor in the periacetabular region, unlike a resection of the ilium or the pubis, imposes a major impairment on the function of the hip joint. It usually necessitates an en bloc resection of the proximal femur and a complex prosthetic reconstruction.

**Pubis**

- The neurovascular bundle passes within the femoral triangle just anterior to the superior pubic ramus. Tumors extending to or arising from the pubic ramus are in close proximity to the femoral artery, vein, and nerve. In addition, the urethra passes straight underneath the symphysis pubis. Vulnerable structures such as a major blood vessel, nerve, or a viscus must be identified and mobilized before resection. By identifying and isolating crucial structures, the surgeon avoids iatrogenic injury during dissection. Establishing the relation of these vulnerable structures to the tumor allows the surgeon to decide whether to proceed with a limb-sparing procedure or perform an amputation, make the necessary preparations for a vascular graft (if needed), and perform a safe resection.

**SURGICAL MANAGEMENT**

**Preoperative Planning**

**Restaging studies**

- Preoperative planning is crucial to obtain an optimal oncologic and functional surgical result.
- Imaging studies are crucial in addressing the following questions: location and extent of the tumor, the type of pelvic resection that is necessary for adequate removal of the tumor, involvement of critical adjacent structures in the tumor mass (ie, ureter, aorta, inferior vena cava, bladder), and the type of reconstruction that can be achieved.
- Plain radiographs, CT scans, MRI scans, bone scans, and 3D-CT angiographs are obtained to access the extent of osseous and soft tissue involvement in all anatomic planes. The status of crucial adjacent structures—bladder, colon, ureter, inferior vena cava, sacral alar, and possible lumbar extent—is reviewed.
- Using angiography and venography, preoperative embolization is considered, and anatomic distortion and vessel occlusion and venous thrombus are assessed.
- Consider possible need for prophylactic ureteral stents if there is evidence of preoperative ureteral obstruction or displacement.
- Medical and anesthesia personnel are consulted to assess medical risk, preoperative laboratory studies, and transfusion needs (eg, prepare red blood cell count, cryo, platelets, and plasma). A risk of major blood loss during surgery is assumed, often equal to one total body transfusion (> 7% body weight in kg).
- Bowel preparation before surgery and ICU reservation also should be considered.
• Orthotic brace is fabricated preoperatively for postoperative use.
• Colostomy planning and training must be considered if there is left colon involvement, or large left-sided pelvic tumors, both of which can be detected preoperatively with contrast-enhanced CT and colonoscopy.
• Appropriate prosthetic implants (eg, total hip replacement vs. saddle prosthesis), bone allograft, or other implants must be ordered.

Positioning
• At the time of surgery all patients should have a Foley catheter and a rectal tube placed. The rectum is sutured closed around the rectal tube to avoid iatrogenic contamination during the operative procedure. During surgery the surgeon may palpate the balloon of the Foley catheter in the bladder and the rectal tube through the wall of the rectum, to assist in proper identification of these structures. This is especially helpful with large pelvic tumors, especially those on the left side.
• Type 1 resection (iliac): the patient is positioned in the lateral decubitus position with an anterior tilt to allow posterior access (FIG 8A–D).
• Type 2 resection (periacetabular): the patient is positioned in the lateral decubitus position for access to both the anterior and posterior pelvis (FIG 8E,F).

FIG 8 • Type 1 pelvic (ilium) resection can be either partial (A), in which only part of the ilium is transected, or complete (B). Partial (C) and complete (D) type 1 resections. E. Type II pelvic (periacetabular) resections. Reconstruction was performed with a saddle prosthesis. F. Type II pelvic resection. G–I. Type III pelvic (pubic) resection. These resections may include the superior pubic ramus (G), inferior pubic ramus, or both rami (H). I. Type III pelvic resection.
Type 3 resection (pelvic floor): The patient is positioned supine with the lower extremity flexed and abducted to provide exposure of the retroperitoneal space, the femoral triangle, the perineum, the symphysis pubis, and the ischiorectal space (FIG 8G–I).

Approach

- The utilitarian pelvic incision is indicated (FIG 9).
- The incision begins at the posterior inferior iliac spine and extends along the iliac crest to the anterior superior iliac spine. It is separated into two arms: one is carried along the inguinal ligament up to the symphysis pubis; the other turns distally over the anterior thigh for one-third the length of the thigh and then curves laterally just posterior to the shaft of the femur below the greater trochanter and follows the insertion of the gluteus maximus muscle. Reflection of the posterior glutus maximus flap exposes the retrogluteal space, the proximal third of the femur, the sciatic notch, the sciatic nerve, the ischium, as well as the supra-acetabular area needed for the superior osteotomy.

Type 1 Resection: Iliac Resection

- The incision for an iliac resection is ilioinguinal, following the iliac crest and curving posteriorly at the level of the sacroiliac joint. It then follows the length of the sacroiliac joint combined with a lateral incision to expose the outer portion of the ilium, sciatic notch, and retrogluteal space.

Type 2 Resection: Periacetabular Resection

- A combination of an anterior retroperitoneal approach and lateral anterior incision along the femur that curves posteriorly is used for a periacetabular resection. A lateral, posterior-based fasciocutaneous flap, called a gluteal flap, is then raised. This permits easy access and visualization of the retrogluteal space; hip joint, sciatic notch, sciatic nerve, and ischium, as well as the supra-acetabular area needed for the superior osteotomy.

Type 3 Resection: Pelvic Floor and Pubic Region

- Three incisions are required for a resection of the pelvic floor and pubic region. The main incision is the retroperitoneal (ilioinguinal) incision to permit retroperitoneal exploration and mobilization of the major vessels and nerves. Two longitudinal incisions are required to develop a distal-based flap of the anterior thigh so as to expose the femoral triangle as well as the adductors attaching to the obturator foramen. One incision follows the perineal crease; the second begins at the lateral portion of the ilioinguinal incision at the level of the anterior superior iliac spine.

Type 1: Iliac Resection

- The patient is placed in the lateral decubitus position with a posterior tilt.
- The utilitarian pelvic incision is used. Its ilioinguinal component is advanced medially to the symphysis pubis, and its posterior arm is brought to the level of the sacroiliac joint (TECH FIG 1A, B).
- All muscle attachments, with the exception of the iliacus and gluteus minimus and portions of the gluteus medius, which are resected en bloc with the tumor, are removed from the iliac crest. The abdominal wall musculature, the sartorius muscle, and the tensor fasciae latae muscle are transected from the iliac crest and reflected away from the ilium. The rectus femoris muscle remains intact. The iliobibial band is transected from its origin from the iliac crest and reflected posteriorly along with the glutus maximus. Large fasciocutaneous flaps are raised and reflected medially and posteriorly.
Chapter 17  OVERVIEW ON PELVIC RESECTIONS: SURGICAL CONSIDERATIONS AND CLASSIFICATIONS

TECH FIG 1 • A. Incision and surgical approach. The entire utilitarian incision is used for type I resection. The posterior fasciocutaneous flap exposes the entire retrogluteal area: the sciatic notch, the sciatic nerve, the abductor muscles, and the hip joint. This approach provides a good exposure of the retroperitoneal space as well as the posterior retrogluteal area and permits a safe resection of the ilium. The ilioinguinal component is advanced medially to the symphysis pubis and posteriorly to the sacrum (B). C. Posterior exposure and muscle releases. The abdominal wall musculature is transected off of the iliac crest. The sartorius and tensor fascia lata muscles are transected from their tendinous insertions and reflected distally. The rectus femoris muscle remains intact. Large fasciocutaneous flaps are raised and reflected medially and posteriorly. The iliotibial band is transected from its origin from the iliac crest and reflected posteriorly along with the gluteus maximus. D. Anterior (retroperitoneal) exposure. The retroperitoneal space is easily exposed and explored through the ilioinguinal component of the incision. The plane between the iliacus and the psoas muscle is developed with caution, because the femoral nerve lies in that space. The psoas muscle and the femoral nerve are reflected medially, and the iliacus muscle is transected through its substance. The femoral nerve is preserved. (continued)
The plane between the iliacus and the psoas muscle is developed cautiously, because the femoral nerve lies in that space. The psoas muscle and the femoral nerve are reflected medially, and the iliacus muscle is transected through its substance (TECH FIG 1C).

The external iliac artery, which lies against the lower margin of the ilium, gives off no major branches along the inner table of the ilium; ligation of large blood vessels is not required, therefore, in type I pelvic resection. Most tumors of the ilium break through the outer table and push the gluteus medius muscle laterally. The gluteus medius muscle is transected through its substance, 2 to 3 cm distal to the inferior border of the tumor (TECH FIG 1D,E). It is important to try to save as much muscle belly as possible because that will be the major component in soft tissue coverage of the pelvic content and will be necessary for reconstruction of the abductor mechanism.

Osteotomy of the ilium is performed using a malleable retractor, which is inserted through the greater sciatic notch, along the inferior border of the inner table, and out just underneath the anterior superior iliac spine, to protect the pelvic viscera. The ilium is transected above the hip capsule, leaving the origin of the rectus femoris muscle and the roof of the acetabulum intact. Care is taken not to enter the hip joint. Insert: The sacroiliac joint is opened from within the pelvis. The iliac vessels must be mobilized and retracted before attempting to open the sacroiliac joint. G. Soft tissue reconstruction. The gluteus medius muscle is sutured to the abdominal wall musculature with the ipsilateral lower extremity in abduction. Dacron tape must be used to reinforce this reconstruction. The suture line also is reinforced by oversewing the tensor fascia lata and sartorius muscles. (Courtesy of Martin M. Malawer.)
anatomically connected, creates a significant tension, which can be reduced by placing the lower extremity in abduction. The suture line is reinforced with the tensor fasciae lata and sartorius muscles with 3-mm Dacron tape (TECH FIG 1G). Closure of the muscle layer must be meticulous, because poor healing and wound dehiscence will expose the abdominal and pelvic contents and will be difficult to manage.

Optional Reconstruction
- It is not necessary to reconstruct the resultant bony defect, although allograft reconstruction has been reported.
- For iliac osseous reconstruction, allograft should be thawed with permanent/tissue culture. Gram stain has a high rate of false positives and should be avoided.
- Cut the allograft after careful sizing and orientation and fix with a 4.5-mm reconstruction plate. Use intraoperative radiographs to confirm screw placement.
- Two deep soft drains (anterior and posterior) are placed deep to the fascial closure.

Type 2: Periacetabular Resection
- The patient is in the lateral decubitus position with posterior tilt to maximize anterior dissection.
- The utilitarian incision is used to expose both the anterior (internal) and posterior (extrapelvic) aspects of the pelvis. The ilioinguinal incision is used to develop the retroperitoneal plane, and the posterior gluteus maximus fasciocutaneous flap is used to develop the retrogluteal space.
- The iliac vessels are mobilized first, and the hypogastric artery is identified and ligated. The sciatic and femoral nerves are identified and protected.
- The level of osteotomy through the ilium is identified from within the pelvis, as are the superior pubic rami. Identification of the superior pubic rami requires mobilization of the external iliac and femoral vessels as they cross the rami (TECH FIG 2).
- A large posterior myocutaneous flap is developed with the gluteus maximus muscle. The gluteus maximus muscle is detached from the iliobibial band and femur to enable it to be retracted posteriorly. This exposes the retrogluteal space: the ilium, sciatic notch, sciatic nerve, and hip joint.
- The ischium is identified through the posterior incision and is osteotomized above the level of the biceps femoris tendon insertion.
- Complete removal of the periacetabulum requires release of the sacrospinous ligament and some of the pelvic floor musculature. An ilioinguinal incision is used with a separate posterolateral hip incision for hip exposure and replacement, posterior column osteotomy, and exposure of the sciatic nerve.
- Three types of osteotomies may be used for periacetabular resection: (1) supra-acetabular osteotomy; (2) superior pubic ramus osteotomy; and (3) ischial osteotomy.

TECH FIG 2 • A. Plain radiograph showing an extremely high-grade malignant fibrous histiocytoma arising from the superior and inferior pubic ramus involving the entire obturator foramen, pelvic floor, and medial and supra-acetabular aspect of the acetabulum (solid arrows). B. Gross specimen following type II/type III pelvic resection. C. Gross specimen following a complete internal hemipelvectomy (type I/type II/type III pelvic resection). D. Radiograph of the resected specimen showing complete involvement of the hemipelvis. The defect superiorly was created by an open biopsy. E. Gross specimen of a combination type II/type III pelvic resection. F. Gross specimen following a type III pelvic resection. A large tumor mass is seen arising from the obturator internus muscle (solid arrows). A, acetabulum; IL, portion of the ilium; IP, inferior pubic ramus and pubis; P, the entire pelvic floor, including the superior and inferior pubic ramus; SP, superior pubic ramus; SY, symphysis pubis. (Courtesy of Martin M. Malawer.)
A total hip exposure is used to identify the sciatic nerve and posterior column. The procedure is begun with dissection of the external rotators and osteotomy of the femoral neck, per total hip procedure.

- Cut the femoral neck at the standard neck length (1.0 cm proximal to the lesser trochanter).
- Incise the hip capsule peripherally with dissection of the sciatic nerve proximally to the sciatic notch.
- The anterior and posterior columns are exposed to allow osteotomy of the acetabulum. Posterior column osteotomy requires careful exposure and retraction of the sciatic nerve and gluteal vessels.

**Reconstruction After Type 2 Resection**

- Several choices are available for reconstruction following a type 2 resection: composite allograft; saddle reconstruction (Link, America); partial pelvic prosthesis (Stryker, Mahwah, NJ); various reconstruction rings with large phalanges; and ischiofemoral arthrodesis. Each has unique techniques, complications, functional deficits, and results.

**Composite Allograft Acetabular Reconstruction**

- Femoral component: ream and place the uncemented femoral component through the posterior lateral approach before proceeding with iliac osteotomy resection.
- Acetabulum: ream the allograft for the acetabular component and place the acetabular component (cement and screws) into the allograft to confirm graft and acetabular orientation in situ with radiography before screw or cement fixation.
- Check acetabulum positioning with radiographs before and after fixation or cementation. Orient the iliac graft before confirming the acetabular orientation, and fix the graft with a reconstruction plate and screws. Use an extended polyethylene acetabular rim and consider a large femoral head (32–36 mm) to improve postoperative stability.
- Closure. Using the inguinal ligaments, reconstruct the abductors, especially if a trochanteric osteotomy was done. Perform pelvic closure at the iliac crest and inguinal canal with wound drainage catheters.

**Type 2: Resection and Reconstruction with Saddle Prosthesis**

**Notchplasty (Tech Fig 3A–C)**

- A notch is created in the remaining ilium using a high-speed burr. The notch should be placed in the thickest region of the remaining bone (usually medial).

**Preparation of the Proximal Femur**

- The proximal femur is prepared as for a standard femoral component. The intramedullary canal of the proximal femur is reamed to accept the largest-diameter stem and allow for a 2-mm circumferential cement mantle. Once reaming is completed, and the appropriate-sized stem (diameter and length) is selected, a distal femoral cement plug is inserted to a depth of 2 cm below the tip of the selected femoral stem. The femoral canal then is irrigated with saline and packed with gauze. Once the cement (polymethylmethacrylate) is prepared, the gauze is removed, and the femoral prosthesis is cemented within the proximal femur.

**Trial Reduction**

- A reduction using trial components is critical in assessing accurate length of the base component (intercalary segment) and determining optimum soft tissue tension (TECH FIG 3D–K). The base component length should be determined by the distance between the ilium and femoral neck cuts, because the length indicated on the base component is the total length from the notch of the saddle to the femoral collar. The base component should be selected so that reduction is barely possible and there is minimum “play” in the reduced joint. The surgeon should be able to reattach the abductor mechanism to its anatomic position on the osteotomized greater trochanter.

- A trial reduction also can determine areas where the saddle component may impinge on the existing notch during intraoperative range of motion. These areas can be further contoured with a high-speed burr to prevent impingement, which may result in limited motion or dislocation. Hip motion (flexion to at least 90 degrees, extension to 30 degrees, abduction to 45 degrees, adduction to neutral, and rotation) should be possible without evidence of impingement or dislocation.

**Abductor Mechanism Reconstruction**

- The osteotomized greater trochanter and abductors are reattached to their original location using cables. If the greater trochanter was included in the resected specimen, the abductor mechanism is reattached to the prosthesis using 3-mm Dacron tapes or a cable system. Soft tissue tension and prosthetic stability are again tested once the abductor mechanism reconstruction is complete. The piriformis and short external rotator muscles are brought forward and reattached to the proximal femur (or prosthesis). The gluteus maximus muscle is then reattached to its insertion using nonabsorbable suture (TECH FIG 3L–N).

- Pelvic closure involves attachment of the inguinal canal and abdominal wall to the symphysis pubis and lateral iliac crest. Soft tissue tension and prosthetic stability are tested again once the abductor mechanism reconstruction is complete. The piriformis and short external rotator muscles are brought forward and reattached to the proximal femur (or prosthesis). The gluteus maximus is then reattached to its insertion using nonabsorbable suture.

- For high type II pelvic resections, reconstruction should be carried out with a partial pelvic prosthesis (Stryker, Mahwah, NJ).

**Type 3 Resection: Pelvic Floor**

- A utilitarian pelvic incision with a perineal extension is used (three-incision approach).
A. Photograph following a periacetabular resection showing the remaining ilium (Il), the sciatic nerve (S), the greater trochanteric osteotomy (G), and the femoral head. B. Intraoperative photograph demonstrating the creation of the deep notch (large arrows). C. Reduction of the saddle prosthesis into the iliac notch (IL). The notch (solid arrows) must be as deep as the saddle and permit approximately 45 degrees of flexion and extension, as well as abduction and adduction. D. Surgical exposure using the utilitarian pelvic incision. E. A large posterior fasciocutaneous flap based medially permits the release of the gluteus maximus. F. Schematic diagram of the mobilization of the periacetabular structures and the three osteotomies that are necessary for a complete resection of the acetabulum. G. Schematic of the “close-up” view of the superior pubic ramus osteotomy. (continued)
The patient is positioned with the ipsilateral hip slightly elevated.

The ilioinguinal component of the utilitarian pelvic incision with a lateral and perineal (medial) extension is used (see Tech Fig 1G). This incision allows exposure and mobilization of the femoral vessels and nerve through a distal-based anterior flap.

Perineal extension of the incision is used to expose the ischium, which is resected through the ischiorectal fossa when the resection is performed for a large pubic lesion.

Large myocutaneous flaps are raised. The spermatic cord is reflected medially. The inguinal ligament is transected from its pubic insertion and reflected laterally.

The neurovascular bundle (ie, the femoral artery, vein, and nerve) is retracted laterally, exposing the origin of the adductor magnus and pectineus muscles, which is transected off the pubis and reflected distally.

Using the lateral component of the incision, the origins of the hamstrings, adductors, and gracilis are transected off the ischium and reflected distally (TECH FIG 4).

The first malleable retractor is placed behind the symphysis pubis, in front of the bladder. The second malleable retractor is placed behind the superior pubic ramus and in front of the inferior pubic ramus, medial or lateral to the ischium, depending on the required oncologic margins (TECH FIG 4C).
Osteotomy through the symphysis pubis and pubic rami is performed. It is important to smooth the sharp bony edges, especially those that lie against the bladder.

Surgical wounds around the groin are notoriously associated with a high incidence of dehiscence and infection. Meticulous wound closure with adequate drainage is, therefore, mandatory. Continuous suction is required for 3 to 5 days. Perioperative intravenous antibiotics are continued until the drainage tubes are removed.

Postoperative mobilization with weight-bearing as tolerated is allowed.

Rarely, reconstruction of the pelvic floor with Marlex (CR Bard, Cranston, RI) mesh is required.

**Type 4 Resection: Hemipelvic**

- Table 1 describes hemipelvic resection, along with other techniques.
- Combined, extended full pelvic dissection from symphysis pubis to sacroiliac joint is required.
- Complete dissection of the sciatic notch, the hip joint, the sciatic nerve, and the femoral vessels is required.
- Pelvic reconstruction is more challenging because of the need for fixation at the sacrum and symphysis pubis and the difficulty in orienting a pelvic graft.
- Some surgeons do not recommend reconstruction but accept 3 inches of shortening and the use of a pelvic long-leg brace.
- A large amount of intraoperative blood loss and hemipelvic graft fixations present significant surgical challenges.
Surgical Vessels

**Technique Position Incision Exposure and Nerves Resection Reconstruction Closure**

**Type 1: Posterior Lateral with Ilioinguinal with External Careful dissection Iliopsoas, Allograft fixation with Abdominal wall ileac resection anterior tilt or without sacral oblique and femoral n. and osteotomy at 4.5-mm plate m. to pelvis with extension abdominal m. vessels; iliac, iliac crest nonabsorbable gluteal vessels sutures and two deep drains (anterior and posterior)**

**PEARLS AND PITFALLS**

**Vascular problems**
- Always have vascular control of the major vessels proximally and distally, both arterial and venous.

**Intraoperative bleeding**
- Severe bleeding usually occurs with venous, not arterial, injuries. Suture and ligate all serious bleeders.

**Thrombosis**
- All patients are at risk to develop an arterial thrombosis during or after surgery and should be evaluated (pulses) carefully during and for the first 72 hours. Always confirm adequacy of hemostasis and distal flow and pulses before leaving the operating room. If there is any question, perform an intraoperative or postoperative angiogram.

**Postoperative bleeding and coagulopathy**
- If bleeding continues, and coagulation factors rule out disseminated intravascular coagulation, strongly consider taking the patient back to the operating room. Alternatively, perform an angiogram with attempt at embolization of the bleeding vessel. The degree and timing of the bleeding are important in determining the correct course of action.
- If massive (≥ 4.0–5.0 L) bleeding occurs during the dissection, pack the wound with local pressure until the patient’s blood pressure stabilizes.
POSTOPERATIVE CARE
- The distal extremity pulses are checked immediately after surgery and every hour for the first 24 hours. Late arterial thrombosis often is due to intimal injuries.
- Persistent wound drainage usually is due to a large retroperitoneal collection. If the wound continues to drain after 4 to 7 days postoperatively, wound irrigation and drainage in the operating room should be considered.
- All postoperative patients should have a pelvic radiograph once a week for the first 2 weeks.
- Postoperative complete blood cell count and laboratory studies daily for the first week then twice per week.
- Postoperative mobilization is highly individualized:
  - Type 1 resection. Abdominal wall to abductors are maintained in abduction for 7 days in bed and then in a pelvic–thigh brace that avoids excessive adduction.
  - Type 2 resection and reconstruction is very variable. Patients with a saddle prosthesis and composite allograft are maintained on partial weight bearing for 3 to 6 months and need a pelvic and thigh brace for 2 to 3 months.
  - Patients with a type 3 resection with or without Marlex reconstructions are kept in bed with the lower extremity in neutral (it is necessary to avoid abduction) to avoid a perineal incision dehiscence. A pelvic and thigh orthosis is used for about 3 months. Full weight bearing can be initiated early if the medial wall of the acetabulum was not involved.

COMPLICATIONS

Early
- Bleeding. Most problems with intraoperative bleeding occur with venous, not arterial, bleeding. Coagulopathy and the need for large blood transfusions are common complications. Coagulation factors, Ca, and Mg should be monitored. Patients should receive packed cells, fresh frozen plasma, platelets, Ca, and Mg as necessary during and after surgery.
- Arterial thrombosis occurs due to intimal flap tear and should be monitored by distal pulse measurement with Doppler, every hour for the first 24 hours. If arterial thrombosis occurs, immediate thrombectomy is required.
- Nerve. Postoperative femoral or sciatic neuropraxia are common and should be observed.
- Ureter/bladder. Patient should be evaluated for intraoperative hematuria or oliguria, which may suggest bladder or ureter injury. Urine output is routinely measured hourly during surgery. The Foley urinary catheter is kept in place for 4 to 7 days.
- Bowel injuries require repair or resection and possible colostomy.
- Major ileus is a common problem following extensive pelvic surgery. The patient should be given nothing by mouth, with a nasogastric tube in place, until appropriate bowel sounds return (usually 3–4 days).

Late Complications
- Infection. Deep infection develops in 20% to 30% of patients following surgery. If such an infection occurs, the patient must be taken back to the operating room, and the prosthesis and allograft must be removed, leaving the limb flail.
- Dislocation. The dislocation rate for a saddle prosthesis is 5% to 10%. This rate may be even higher for “composite” reconstructions.
- Failure of the allograft may take the form of fracture through the allograft or failure of fixation.
- Prosthesis failure includes failure of the reconstruction ring, acetabular cup, screws, and plate.
- Morbidity and mortality after pelvic resection remains high. Hemipelvectomy may be required due to local recurrence, infection, or uncontrolled bleeding.

REFERENCES

BACKGROUND
- For patients with metastatic periacetabular disease confined to the supra-acetabular region, resection and reconstruction avoids hip joint replacement.
- The goal of treatment is to alleviate pain and ensure ambulation as soon as possible after surgery, with minimal perioperative morbidity and mortality.
- Periacetabular lesions may be classified according to Harrington’s classification. Supra-acetabular lesions are categorized as class I.
- Surgical options include extra-articular curettage and fixation versus intra-articular acetabular curettage and reconstruction with an acetabular prosthetic component, known as total hip replacement.
  - The extra-articular approach requires minimal surgical intervention (<1 hour, with minimal blood loss), a shorter postoperative hospital stay, and lower post–hip arthroplasty risk of infection and instability.
  - The intra-articular approach, or total hip replacement, is a more expansive, definitive approach, with a mean blood loss of 1800 mL, mean operative time of 140 minutes, and average hospital stay of 14 days.1

ANATOMY
- Metastatic bone disease usually does not invade into cartilage. Therefore, the acetabular cartilage usually is spared by periacetabular lesions. After curettage, fixation of the lesion provides ample support for the cartilage without violating the joint (analogous to curettage and cementation of giant cell tumors).
- Reconstruction should take into account the concavity of the hip cartilage.

INDICATIONS
- Metastatic periacetabular lesions may present as pain on weight bearing.
- The treatment of choice for most of these lesions is radiation therapy.
- Surgical treatment is reserved for impending pathological fractures and painful lesions resistant to radiation therapy (FIG 1).
  - Harrington class I lesions have extensive tumor invasion without loss of structural integrity of the acetabulum. Minimal medial wall disease is present.
  - Not indicated if the ipsilateral femoral head is involved with tumor.

IMAGING AND OTHER STAGING STUDIES
Imaging
- Plain radiographs and CT scans of the pelvis and hip joint are necessary to define the extent of the lesion accurately.
- Three-dimensional CT reconstructions have been used more recently to show remaining bone stock accurately.
- MRI studies are helpful in defining the continuity of the acetabular cartilage (FIG 2A).
- Bone scan is needed to rule out concomitant metastatic lesions to the ipsilateral femur (FIG 2B).
- Angiography and embolization should be strongly considered in metastases from vascular lesions such as renal cell and thyroid carcinoma.

Biopsy
- For metastatic disease, biopsy is performed at the time of surgery. A frozen section typically provides adequate diagnostic information.

SURGICAL MANAGEMENT
- A CT scan is done preoperatively to access localized tumor to supra-acetabular area with minimal medial wall involvement.
- The patient is placed in the lateral decubitus position.
- The skin incision is made from the posterior third of the iliac crest to the greater trochanter (FIG 3A).
- The gluteus maximus is detached from the iliotibial band and retracted to expose the retrogluteal space. Care is taken not to open the hip joint.
- The sciatic nerve should be picked up as it exits below the piriformis muscle and should be tagged with a vessel loop. The sciatic notch is identified, and the nerve is protected (FIG 3B).
- The iliac bone superior to the acetabulum may then be exposed by retracting the gluteus medius and minimus muscles anteriorly. Care should be taken not to injure the superior and inferior gluteal vessels.
FIG 1 • A. Supra-acetabular metastatic lytic lesion. Joint contour is preserved. B. Supra-acetabular defect in a pelvic model. C. Reconstruction of the defect.

FIG 2 • A. T2-weighted MRI scan showing the preserved cartilage border of the right hip joint. B. Technetium Tc 99m bone scan showing uptake in the supra-acetabular region. No uptake is seen in the ipsilateral femur or medial acetabular wall.

FIG 3 • A. The patient is placed in the lateral decubitus position. The skin incision is carried from the iliac crest to the proximal femur. B. Exposure. The sciatic nerve is tagged and protected, and the sciatic notch is identified. The hip joint is left untouched. The iliac bone is exposed by reflecting the gluteus medius and minimus muscles anteriorly.

CURETTAGE AND RECONSTRUCTION

- The lesion is unroofed and curetted (TECH FIG 1A).
- The acetabular cartilage and the remaining subchondral bone are supported with a highly cross-linked polyethylene tibial liner, chosen for its concave shape. It is cut to size (TECH FIG 1B).
- The remaining defect is then packed with polymethylmethacrylate (TECH FIG 1C,D).
- Additional support may be achieved with Steinmann pins inserted in an antegrade or retrograde fashion between the iliac crest and the area of the lesion if the inner wall of the ilium has been destroyed.
- A perineural catheter is inserted into the sciatic nerve sheath for postoperative pain management. Through this catheter, 0.25% bupivacaine can be administered for up to 72 hours postoperatively.
POSTOPERATIVE CARE
- Immediate weight bearing should be allowed, because the structure should be stable and virtually pain-free.

OUTCOMES
- Full weight bearing permitted
- Minimal blood loss (<300 mL)
- No infections to date
- Avoids the possible complications of total hip replacement
- Rare tumor progression

COMPLICATIONS
- Risk of postoperative infection is minimal due to the minimal extent of the surgery.

REFERENCES
BACKGROUND

- The gluteus maximus (buttock) is a common site for high- and low-grade soft tissue sarcomas. The gluteus maximus is a “quiet area” for soft tissue sarcomas and rarely become symptomatic until they are extremely large. Traditionally low- and high-grade soft tissue sarcomas of the buttock were treated with a posterior cutaneous flap hemipelvectomy. Today, most sarcomas of this muscle can be resected with safe margins; hemipelvectomy is not required. Advances in limb sparing surgical procedures have reduced the need for hemipelvectomy for tumors in this region.
- Tumors of the gluteus maximus are often confined to this muscle and do not extend to the underlying retrogluteal space or involve the sacrum or femur. The most significant structure in the retrogluteal space that must be evaluated is the sciatic nerve. Minimal reconstruction is required. During the postoperative period it is important to take measures to prevent the formation of large postoperative seromas. The functional outcome of a resection of the gluteus maximus is a minimal deficit in hip extension only. The gait is normal.
- A hemipelvectomy rarely is required for a soft tissue sarcoma of the buttock unless it is extremely large or accompanied by fungation, infection, or extension into the ischiorectal space, pelvis, and hip. Direct sacral or iliac bone involvement, which is rare, often necessitates an amputation.
- Today about 90% of soft tissue sarcomas arising in the buttock can be resected and treated adequately by a limb sparing surgery. Low-grade soft tissue sarcomas of the gluteus maximus usually require surgery only; high-grade soft tissue sarcomas in this region, like those in other anatomic areas, are also usually treated with chemotherapy and/or radiation preoperatively and/or postoperatively.
- The authors favor the use of induction chemotherapy followed by a limb-sparing resection when possible for high-grade soft tissue sarcomas. The field is treated with postoperative radiation if required.
- The major indications for an amputation are extremely large sarcomas that involve the adjacent bone, the sciatic nerve, or the ischiorectal fossa.

ANATOMY

- The gluteus maximus arises from the sacral lamina, iliac crest, and ischium. It passes obliquely to its insertion onto the proximal portion of the iliotibial band. This insertion begins above the greater trochanter, passes 4 to 5 cm below the greater trochanter, and then attaches to the adjacent femur. The area underneath the gluteus maximus is termed the retrogluteal space. This area consists of the posterior hip musculature, including the external rotators and portions of the gluteus medius muscle. The sciatic nerve lies in the retrogluteal space. The gluteus maximus does not attach to the retrogluteal structures as it passes over them. This permits easier surgical dissection of the retrogluteal plane and preservation of the sciatic nerve in many situations.
- As it passes from the sacrum to the femur, the gluteus maximus covers the sacroiliac joint and the sacrospinous and sacrotuberous ligaments, as well as a portion of the ischiorectal fossa.
- Most importantly, the sciatic nerve exits the pelvis through the sciatic notch and passes inferiorly to the piriformis muscle. This nerve lies in close proximity to the posterior fascia of the gluteus maximus; therefore, large tumors of the gluteus maximus may involve the sciatic nerve. The sciatic nerve, however, rarely is involved by the tumor; most often it is displaced around the capsule or pseudocapsule. The inferior gluteal vessels pass below the piriformis muscle to enter the midpoint of the gluteus maximus. The inferior gluteal vessels are routinely ligated.

INDICATIONS

- A gluteus maximus resection is indicated for patients with low- and high-grade sarcomas confined to the gluteus maximus.

CONTRAINDICATIONS

- Large tumors that involve the true pelvis or ischiorectal space
- Involvement of the sacrum or ilium
- Sciatic nerve involvement (although, on occasion, the sciatic nerve may be resected)
- Pelvic extension through the sciatic notch

IMAGING STUDIES

Computed Tomography and Magnetic Resonance Imaging

- CT and MRI are most useful in determining the extent of tumor involvement of the gluteus maximus
- Close evaluation determines the involvement of the adjacent sacrum, femur, and sciatic nerve. Attention should be placed on the evaluation of the structures of the retrogluteal space, including the hip joint and sciatic nerve, and ischiorectal fossa. Buttock tumors may extend into the pelvis through the sciatic notch.

Bone Scan

- Tumor involvement may extend to the crest of the ilium, the sacrum, and the proximal femur. These areas should be evaluated by bone scintigraphy.

Angiography

- Angiography is not routinely performed when evaluating tumors of the gluteus maximus. It may be useful in preoperative embolization or preoperative intra-arterial chemotherapy.

Biopsy

- The biopsy site must be in line with the incision for a hemipelvectomy, should one be required. Surgeons performing
a biopsy of tumors of the buttock must, therefore, be familiar with the surgical incisions for both posterior flap and anterior flap hemipelvectomy (see Chaps. ON-21 and ON-22).

The anterior flap hemipelvectomy, as described by Sugarbaker et al., is preferred for large sarcomas of the buttock area. In this procedure the entire musculature and skin are removed with the amputation, and the anterior myocutaneous flap, consisting of the quadriceps muscle, is used to close the defect.

If a posterior flap is used, care must be taken not to contaminate the posterior skin or fascia. The biopsy site must, therefore, be along the lateral aspects of a posterior incision and must avoid the greater trochanter, sciatic nerve, ischiorectal fossa, and greater trochanter.

**BUTTOCKECTOMY**

- A large curvilinear incision is made beginning at the posterior aspect of the crest of the ilium, curving distally following the gluteus maximus muscle along the iliotibial band (TECH FIG 1A,B), passing over the greater trochanter to about 6 cm distal, and then curving posteriorly back toward the inner aspect of the thigh along the gluteal fold. This incision makes it possible to elevate a large posterior flap.

To determine resectability or operability, the sciatic nerve is identified distal to the resection site. It can be identified between the medial and lateral hamstring muscles or just lateral to the ischium before it passes underneath the gluteus maximus muscle. The nerve is palpated below the gluteus maximus muscle toward the piriformis muscle (TECH FIG 1C).

- The gluteus maximus is detached from the iliotibial band throughout its length and from the femur distally. This muscle is then flapped medially to expose the inferior gluteal vessels and nerve, which are then ligated. The sciatic nerve is displaced anteriorly to protect it during the dissection.

- Removal of the gluteus maximus involves detaching this muscle from the sacrotuberous and sacrospinous ligaments, as well as the lamina and sacral alar (TECH FIG 1D).

- To prevent a large postoperative seroma, the large posterior fasciocutaneous flap must be tacked down to the remaining underlying muscle very carefully. Multiple large drains are used (TECH FIG 1E).

- The patient remains supine for 72 hours to prevent the development of a seroma.

---

**TECH FIG 1 • A.** A lateral position is used. The affected extremity is prepped free from the abdominal wall to the foot. The incision extends along the iliac crest and encompasses the biopsy site by 2 to 3 cm and then extends along the greater trochanter and along the gluteus maximus skinfold. The incision permits wide excision of the underlying gluteus maximus muscle and early exploration and preservation of the sciatic nerve. If the tumor is unresectable, an anterior flap hemipelvectomy is required. **B.** A fasciocutaneous flap is elevated and dissected with the electrocautery toward the origin of the gluteus maximus muscle (from the sacrum). This permits exposure of the entire gluteus maximus muscle. The biopsy site is left en bloc with the gluteus maximus muscle. If the tumor is extremely large, only a subcutaneous flap is used, with the deep fascia remaining on the tumor side. **C.** The retrogluteal space, consisting of the hip rotators, abductor muscles, and the sciatic nerve, is seen in this illustration. The gluteus maximus is mobilized from inferior along the deep posterior thigh fascia and released from the iliotibial band up to the iliac crest. It is then dissected to its origin along the sacral alar and the sacrospinous and sacrotuberous ligaments. The sciatic nerve is explored initially by the surgeon placing his hand under the gluteus maximus to ensure that the nerve is free from the tumor. *(continued)*
POSTOPERATIVE CARE

- Postoperative radiation therapy is required for high-grade tumors once the flaps are well healed (4 to 6 weeks after surgery).
- Postoperative chemotherapy is given following the radiation therapy.

OUTCOMES

- The only deficit following gluteus maximus resection is weakness with hip extension. Secondary hip extensors enable some hip extension and the patient’s gait is virtually normal.
- If the sciatic nerve requires resection there is loss of foot and ankle control, so that the patient requires an ankle-foot orthosis.
- Depending on the level of the sciatic nerve resection, the first branch to the biceps femoris may be intact. If that is the case, good knee flexion will be retained. Knee flexion also depends on the sartorius muscle (innervated by the femoral nerve), the gracilis muscle (innervated by the obturator nerve), and the two heads of the gastrocnemius muscle that insert across the knee joint.

COMPLICATIONS

- The most common postoperative complication is the development of a large seroma, because there is a large dead space with only a subcutaneous flap on top. We have used the quadratus femoris muscle rotated over the sciatic nerve for soft tissue coverage of the nerve.
- Similarly, the piriformis is rotated distally. The flap is carefully tacked down throughout its course in its midportion to eliminate “dead” space. One 20-gauge chest tube and two Jackson-Pratt drains are used, and the remaining portion of the flap is closed. A compressive dressing is utilized for 72 hours.
- In the case of recurrent sarcomas of the buttocks, tumor fungation, massive contamination, or extensive tumor involvement of the adjacent structures, an anterior flap hemipelvectomy is recommended (see Chap. ON-22 for a discussion of this procedure).

REFERENCE

BACKGROUND

- Metastatic tumors of the pelvis may cause pain and a major loss of function and weight-bearing capacity. Due to the relatively large size of the pelvic cavity, the elastic nature of the organs it contains, and its surrounding muscles, tumors at that site usually reach considerable size before causing symptoms. While some locations of metastases within the pelvis have no impact on pelvic stability and function (eg, ilium, pubis), tumors of the posterior ilium may pose a threat to lumbosacral integrity, and tumors of the acetabulum may profoundly impair hip function and the weight-bearing capacity of the lower extremity.
- Both primary sarcomas and metastatic tumors usually present with considerable extension into the soft tissues. Due to their inherent sensitivity to radiation therapy, however, the surgical management of metastatic lesions does not require en bloc resection of overlying muscles, and microscopic residua are treated with adjuvant radiation. The complex anatomy of the pelvic girdle mandates detailed preoperative imaging, planning of exposure and reconstruction technique, and careful and meticulous execution of the surgical procedure.
- Pelvic metastases are treated either with curettage and reconstruction with cemented hardware or by wide resections. These procedures are grouped together and termed pelvic resections, the classification of which is attributed to Enneking and is based on the resected region of the innominate bone: type I, ilium; type II, periacetabular region; type III, pubis. En bloc resection of the posterior ilium with the sacral ala is classified as either an extended type I or type IV resection (FIG 1).

ANATOMY

Ilium

- The iliac crest is the attachment site for abdominal wall musculature and quadratus lumborum (FIG 2).
- The iliacus muscle overlies the inner iliac table, and the femoral nerve lies medial to it in the groove between the iliacus and the psoas muscle.
- Gluteal muscles overlie the outer iliac table.

Acetabulum

- The acetabulum provides the upper-medial mechanical support of the hip joint.
- No muscle attachments connect to the acetabulum.

Pubis

- Hip adductors take their origin from the inferior aspect of the pubis.
- The neurovascular bundle runs along the anterior aspect of the pubis.
- The urinary bladder attaches to its posterior wall.

INDICATIONS

- Pathological fracture of the acetabulum
- Impending pathological fractures of the acetabulum, which are defined as lesions that extend to the acetabular roof and are associated with cortical destruction and considerable pain on weight bearing
- Intractable pain associated with locally progressive disease that has shown inadequate response to narcotics and preoperative radiation therapy
- Solitary bone metastasis, in selected patients

IMAGING AND OTHER STAGING STUDIES (FIG 3)

- Plain radiographs and CT of the pelvis and hip joints are mandatory to evaluate the full extent of bone destruction, soft tissue extension, and integrity of the hip joint. MRI rarely adds additional information; rather, it is indicated in lesions that have diffused intramedullary extension, which is commonly underestimated by CT, such as multiple myeloma. Total body bone scintigraphy is done for detecting synchronous metastases elsewhere in the skeleton. At the conclusion of imaging, the surgeon should be able to answer the following questions:
  - What is the full extent of bone destruction and soft tissue extension that are related to the tumor? Is the lesion an impending fracture? If not, it probably should be treated nonsurgically.
  - What incision should be used to obtain optimal exposure?
  - What would be the best technique for resection and reconstruction, if required?
  - Are there additional skeletal metastases and, if so, can they be managed by nonoperative techniques or do they require surgery?
  - Hypervascular lesions (eg, metastatic renal cell or thyroid carcinomas) can bleed profusely and cause life-threatening blood loss within a few minutes upon tumor exposure and curettage. Preoperative embolization of these tumors is strongly advised to reduce intraoperative blood loss.4,5

SURGICAL MANAGEMENT

Positioning

Types I through III Resection

- The patient is placed supine on the operating table with the ipsilateral hip slightly elevated.

Type IV Resection

- The patient is placed in a true lateral position with the affected side of the pelvic girdle uppermost. The operating table is bent with the breakage point just below the contralateral hip: such a position widens the space between the iliac crest and the lower aspect of the chest wall, allowing a comfortable approach and easier maneuvering at that site (FIG 4).
FIG 1 • Metastatic tumors of the ilium, periacetabular region, pubis, and posterior ilium require types I, II, III, and IV pelvic resections, respectively.

FIG 2 • Muscle attachments and relevant structures around the innominate bone.

FIG 3 • Plain radiographs and CT scans with coronal reconstruction showing acetabular metastases with their most pronounced cortical destruction at the lateral acetabular wall (A–C) and medial acetabular wall (D–F). Lesions in the former area are exposed after reflection of the glutei from the outer iliac table; those from the latter area are exposed after reflection of the iliacus from the inner iliac table (see Incision and Exposure: Acetabulum).
Chapter 20  SURGICAL MANAGEMENT OF METASTATIC BONE DISEASE: PELVIC LESIONS

The most useful approach to pelvic resections is the utilitarian pelvic incision (TECH FIG 1A). All or part of the incision can be used for adequate exploration and resection of pelvic girdle metastases. The incision begins at the posterior inferior iliac spine and extends along the iliac crest to the anterior superior iliac spine. It is then separated into two arms: one extends along the inguinal ligament up to the symphysis pubis, and the other turns distally over the anterior thigh for one-third the length of the thigh and then curves laterally just posterior to the shaft of the femur below the greater trochanter and follows the insertion of the gluteus maximus muscle.

Reflection of the posterior gluteus maximus flap exposes the proximal third of the femur, the sciatic notch, the sacrotuberous and sacrospinous ligaments, the origin of the hamstrings from the ischium, the lateral margin of the sacrum, and the entire buttock. Posteriorly, the incision extends along the posterior iliac crest, posterior-superior iliac spine, and ipsilateral hemisacrum (TECH FIG 1B).

**Type I Resection**
- The middle component of the utilitarian incision is used to expose the iliac crest. Using electrocautery, the glutei are detached and reflected from the outer iliac table. The iliacus muscle is similarly detached and reflected from the inner table (TECH FIG 2).

**Type II Resection**
- For lesions with lateral cortical destruction, the middle component of the utilitarian incision, up to the anterior superior iliac spine with a 5-cm extension along the inguinal arm of the incision, is used. Electrocautery is applied to detach and deflect the iliacus from the inner iliac table, exposing the medial wall of the acetabulum (TECH FIG 4).

**Type III Resection**
- For lesions with medial cortical destruction, the middle component of the utilitarian incision, from the anterior superior iliac spine to 2 cm across the

**EXPOSURE**

**Type I Resection**
- The middle component of the utilitarian incision is used to expose the iliac crest. Using electrocautery, the glutei are detached and reflected from the outer iliac table. The iliacus muscle is similarly detached and reflected from the inner table (TECH FIG 2).

**Type II Resection**
- For lesions with lateral cortical destruction, the middle component of the utilitarian incision, up to the anterior superior iliac spine with a 5-cm extension along the lateral thigh arm of the incision, is used. Electrocautery is applied to detach and reflect the glutei from the outer iliac table, exposing the lateral wall of the acetabulum (TECH FIG 3).

**Type III Resection**
- The inguinal component of the utilitarian incision, from the anterior superior iliac spine to 2 cm across the
symphysis pubis, is used for type III resection. The neurovascular bundle is isolated, marked with vessel loops, and mobilized. The retropubic space is exposed, and a pad is inserted between the urinary bladder and the pubis. Muscle attachments are then detached from the inferior aspect of the pubis (TECH FIG 5).

**Type IV Resection**

- The posterior component of the utilitarian incision is used for type IV resections. Electrocautery is applied to detach the glutei from their origin at the posterior iliac crest and to reflect them (TECH FIG 6).
Exposure of an acetabular metastasis that has caused lateral cortical destruction is accomplished using the middle component of the utilitarian incision up to the anterior superior iliac spine, with a 5-cm extension along the lateral thigh arm of the incision. B, C. Using electrocautery, the glutei are detached and reflected from the outer iliac table, exposing the lateral wall of the acetabulum.

Exposure of an acetabular metastasis with medial cortical destruction is achieved by using the middle component of the utilitarian incision up to the anterior superior iliac spine, with a 5-cm extension along the inguinal arm of the incision. B, C. Using electrocautery, the iliacus is detached and reflected from the inner iliac table, exposing the medial wall of the acetabulum.
TECH FIG 5 • A. Exposure of a pubic metastasis is accomplished with the inguinal component of the utilitarian incision, from the anterior superior iliac spine to 2 cm across the symphysis pubis. B. The affected bone is reached after isolation and mobilization of the neurovascular bundle from the anterior aspect of the pubis, reflection of the urinary bladder from its posterior aspect, and detachment and reflection of the adductors origin from its inferior aspect.

TECH FIG 6 • A,B. Exposure of a metastasis at the posterior ilium is achieved by using the posterior component of the utilitarian incision. C. The glutei are detached from their origin from the posterior iliac crest and outer table. D. Reflection exposes the outer iliac table.
TUMOR REMOVAL

Type I Resection
- Type I resections involve an osteotomy of the ilium around the lesion. Margins of 1 to 2 cm are sufficient for resection of metastases at that site (TECH FIG 7). Tumor curettage is neither feasible nor justified at that site, because a resection of the ilium that does not impair acetabular or sacroiliac joint integrity rarely has an impact on function.

Type II Resection
- A wide cortical window is made above the lesion (TECH FIG 8A). Gross tumor is removed with hand curettes (TECH FIG 8B, C). Curettage should be meticulous and leave only microscopic disease in the tumor cavity. It is

TECH FIG 7 • Plain radiograph showing the ilium following a type I resection. The sacroiliac joint and the acetabulum are intact, and function is, therefore, expected to remain unimpaired.

TECH FIG 8 • A. A wide cortical window is created. B, C. Gross tumor is meticulously removed with hand curettes, leaving only microscopic disease. D, E. Curettage is followed by high-speed burr drilling of the tumor cavity.
followed by high-speed burr drilling of the tumor cavity walls (TECH FIG 8D,E).

When the entire acetabulum is destroyed and no cortices are left to contain an internal fixation device and cement, a formal resection is done in the same manner as for primary sarcomas of bone (see Chaps. ON-17 and ON-18). The incision is extended along the upper thigh, the joint capsule is opened, the femur is dislocated, and an acetabular osteotomy and resection are carried out.
Type III Resection

- A longitudinal cortical window with oval edges is made above the lesion, and tumor curettage and high-speed burr drilling are done in the same manner as in a type II resection (TECH FIG 9).
- When the pubis is destroyed and no cortices are left to allow curettage and burr-drilling, the incision is extended to exposed intact cortices from both sides of the lesion, followed by formal resection of the pubic segment.

Type IV Resection

- A longitudinal cortical window with oval edges is made above the lesion, and tumor curettage and high-speed burr drilling are done in the same manner as in a type II resection (TECH FIG 10).
- When the posterior ilium is destroyed and no cortices are left to allow curettage and burr-drilling, wide resection of the posterior iliac segment is carried out. These resections commonly require the en bloc removal of the adjacent component of the sacroiliac joint and potentially can impair stability of the posterior pelvic girdle.

MECHANICAL RECONSTRUCTION

Type I and II Resection

- Type I resections require no reconstruction.
- After completion of tumor removal with burr-drilling, the tumor cavity is reconstructed with cemented Steinmann pins, which are introduced through the iliac crest. Following placement of the pins tips against the subchondral bone, the tumor cavity is filled with cement (TECH FIG 11A–C).

TECH FIG 11 • A,B. Steinmann pins are introduced through the iliac crest into the tumor cavity up to the subchondral bone. Following placement of the pins, the tumor cavity is filled with bone cement. C. Plain radiograph showing the acetabular cavity reconstructed with cements Steinmann pins. D. Deficient articular cartilage may be reconstructed with a polyethylene insert.
Acetabular metastases may destroy the subchondral bone and dissociate the articular cartilage. In such cases, reconstruction of the articulating surface of the acetabulum can be done with a prosthetic polyethylene insert that has been shaped with a high-speed burr to match the convexity of the femoral head (TECH FIG 11D).

Two courses are available following resection of the acetabulum: (1) reconstruction with a saddle prosthesis; or (2) no reconstruction, leaving a flail extremity.

**Type III Resection**

Following curettage, the tumor cavity is filled with cement, which does not contribute to pelvic stability but allows easier determination of tumor extent on the postoperative imaging studies and subsequent planning of radiation fields, as well as early detection of local tumor recurrence at the cement–bone interface. No reconstruction is required if resection of a pubic segment had been performed.

**Type IV Resection**

Following curettage, the tumor cavity is filled with cement, the purpose of which is similar to cementation of a pubic defect.

Small defects of the sacroiliac joints do not require reinforcement. Medium-sized defects, however, require such reinforcement with a plate to prevent dissociation of the joint. Complete resection of the sacroiliac joint compromises stability of the posterior pelvic girdle.

Gradual upward migration of the ilium on weight-bearing as well as limb-length discrepancy is likely to occur (TECH FIG 12). Traction of the lower extremity followed by a protected weight-bearing protocol is implemented to reduce the extent of limb-shortening.

**SOFT TISSUE RECONSTRUCTION AND WOUND CLOSURE**

- The glutei and iliacus are sutured over the innominate bone, and both are then sutured to the abdominal wall musculature (TECH FIG 13). These three muscle groups must be attached properly: correct restoration of muscle origin attachment allows function of the glutei and iliacus muscles; and restoration of abdominal wall continuity prevents herniation of the pelvic viscera to the flank.

- The surgical wound is closed over suction drains, and an abduction pillow is used to enable wound healing with minimal stress at the muscle suture line. In the case of a complete resection of the sacroiliac joint and loss of posterior pelvic continuity, skin traction is used to pull the extremity and avoid limb shortening.
TECH FIG 13 • Plain radiograph (A) and CT scan (B) showing metastatic carcinoma of the left ilium. C. Intraoperative photograph showing the remaining iliac stump following osteotomy (the femoral nerve is lifted with a vessel loop and a clamp is passed through the sciatic notch). D. The glutei are sutured to the iliacus muscle to cover the iliac stump, and both are sutured to the abdominal wall musculature to avoid herniation of the pelvic viscera into the flank.

PEARLS AND PITFALLS
- Detailed preoperative imaging and anatomic tumor classification
- Choice of resection type and extent (curettage vs. resection) and technique of reconstruction, if required
- Preoperative embolization of hypervascular lesions
- Use of the appropriate component of the utilitarian incision for wide tumor exposure
- Tumor removal by curettage and high-speed burr drilling; resection when curettage is not feasible
- Reconstruction with cemented hardware
- Functional reconstruction of muscle groups
- Early ambulation with unrestricted weight bearing, except for patients who had complete resection of their sacroiliac joint
- Postoperative radiation therapy

POSTOPERATIVE CARE
- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. Rehabilitation should include early ambulation with unrestricted weight bearing as well as passive and active range-of-motion of the hip joint.
- In complete resections of the sacroiliac joint, skin traction is applied for the first 10 postoperative days, and weight bearing is allowed only after 3 weeks postsurgically have passed. This protocol allows the formation of scar tissue around the sacroiliac defect, which may decrease the extent of iliac migration.
- Once the wound has healed, usually 3 to 4 weeks after surgery, patients are referred to adjuvant radiation therapy.

OUTCOMES
- Most patients who undergo resection of pelvic metastases experience a substantial relief of pain and are able to ambulate with full weight bearing. Most of them do not, however, reach their full functional capability because of a relatively slow recovery and muscle weakness due to their progressing oncologic disease and general wasting.
- Hardware failures rarely are seen if internal fixation devices have been chosen correctly, used properly, and reinforced with
cement. Local recurrence rates are less than 10% as long as there has been adequate tumor removal and if postoperative radiation was administered.\textsuperscript{2,3}

**COMPLICATIONS**

- Deep infection
- Wound dehiscence due to poor nutritional and catabolic states
- Deep vein thrombosis
- Sacroiliac dissociation and upward migration and shortening of lower extremity on weight bearing
- Herniation of pelvic viscera to the flank
- Local tumor recurrence

**REFERENCES**

BACKGROUND

Despite increasingly effective chemotherapy and advances in limb-sparing surgery around the pelvis and hip, hindquarter amputation (hemipelvectomy) often remains the optimal surgical treatment for primary tumors of the upper thigh, hip, or pelvis.

Hemipelvectomy may also be life-saving for patients with massive pelvic trauma or uncontrollable sepsis of the lower extremity, and it can provide significant palliation of uncontrollable metastatic lesions of the extremity. An intimate knowledge of the pelvic anatomy (FIG 1A,B) and a systematic approach to the surgical procedure are required to minimize the intraoperative and postoperative morbidity associated with this demanding procedure.

Early descriptions of the surgical technique of hemipelvectomy emphasized the importance of careful selection of patients and immediate replacement of blood loss. Ligation of the correct pelvic vessels is crucial to a successful outcome. The importance of this fact is indicated by the tumor. Reference to easily palpable and visual landmarks helps identify critical structures.

The advent of limb-sparing pelvic resections has necessitated a distinction between internal and external hemipelvectomy, depending on whether preservation of the ipsilateral limb is performed. Confusion caused by the term “internal hemipelvectomy” can be avoided by use of a standardized classification for pelvic resection.

Sugarbaker and Ackerman and others have shown the utility of a myocutaneous pedicle flap based on the femoral vessels and anterior compartment of the thigh for closure of the wound in patients with tumor involving the posterior buttock structures. This procedure has been termed an “anterior flap hemipelvectomy” to distinguish it from the more common “posterior flap hemipelvectomy.” Anterior flap hemipelvectomy is indicated for tumors that involve the buttock and for selected patients who require a well-vascularized flap for coverage.

There are subtypes of the posterior flap hemipelvectomy. The term “classic hemipelvectomy” is used to refer to amputation of the pelvic ring via disarticulation of the pubic symphysis and the sacroiliac joint, division of the common iliac vessels, and closure with a posterior fasciocutaneous flap (FIG 1C).

Classic hemipelvectomy is typically necessary for large tumors that arise within the pelvis. “Modified hemipelvectomy” refers to a procedure that preserves the hypogastric (internal iliac) vessels and the inferior gluteal vessels supplying the gluteus maximus, permitting creation of a vascularized myocutaneous posterior flap for wound closure. This term also describes variations from the classic operation, including resection through the iliac wing or contralateral pubic rami.

Modified hemipelvectomy is most commonly performed for tumors involving the thigh or hip when a limb-sparing alternative is contraindicated. “Extended hemipelvectomy” refers to a resection of the hemipelvis through the sacral alar and neural foramina, thereby extending the margin for tumors that approach or involve the sacroiliac joint (FIG 2).

Regardless of the type of flap created for closure, the term “compound hemipelvectomy” is used to describe resection of contiguous visceral structures such as bladder, rectum, prostate, or uterus. (Tumor suspected of extending into viscera or extremely large tumors filling the pelvic fossa can be approached through an intraperitoneal incision.)

ANATOMY

The skeletal anatomy and contents of the pelvis are complex and difficult to visualize without direct experience. Major portions of the gastrointestinal tract, the urinary tract, the reproductive organs, and the neurovascular trunks to the extremities all coexist within the confines of the bony pelvis.

Understanding the three-dimensional anatomy is essential to identifying and protecting these structures during a hemipelvectomy (see Fig 1A–C). The normal anatomy may be distorted by the tumor. Reference to easily palpable and visual landmarks helps identify critical structures.

The surgical approach to a hemipelvectomy is based on sequential exposure and identification of these landmarks and structures.

Bony Anatomy

The basic pelvic bony anatomy is best thought of as a ring running from the posterior sacrum to the anterior pubic symphysis. Major joints include the large, flat sacroiliac joints, the hip joints, and the pubic symphysis. The hip joint is easily located by motion of the extremity; the other joints are easily located and identified by palpation. Other easily palpable bony prominences include the iliac crest, the anterior superior iliac spine, the ischial tuberosity, and the greater trochanter of the femur.

These landmarks are essential in creating rational skin incisions during the procedure. Likewise, identification of internal bony landmarks helps localize adjacent structures.

The lumbosacral plexus is found by palpating the sacroiliac joint, the sciatic nerve and gluteal vessels are found under the sciatic notch, and the urethra is found under the arch of the pubic symphysis.

Vascular Anatomy

Ligation of the correct pelvic vessels is crucial to a successful amputation. The importance of this fact is indicated by the
classification scheme, in which the level of ligation determines the type of amputation to be performed. As the abdominal aorta and vena cava descend into the pelvis they bifurcate, creating the common iliac arteries and veins. This bifurcation typically occurs at L4, with the lower bifurcation occurring at S1. The left-sided aorta and the iliac and external iliac arteries remain anterior to the major veins throughout the pelvis. The internal iliac artery (hypogastric artery) bifurcates from the posterior surface of the common iliac artery as it travels down toward the sciatic notch.

- Tumor masses within the pelvis can distort this anatomy, making it mandatory to visualize and isolate each of the vessels before performing a ligation (see Fig 1A).
- The internal iliac (hypogastric) vessels supply the pelvic floor, rectum, bladder, and prostate, as well as the gluteal muscles. Ligation of this vessel will not jeopardize the internal

---

**FIG 2**  •  A. CT scan showing a large chondrosarcoma arising from the left proximal femur. Benign osteochondroma is on the ipsilateral femur. This patient had multiple hereditary osteochondromas. This is one of the more common indications for performing a hemipelvectomy. Chondrosarcoma is the most common malignant tumor of the pelvis.  
B. Pathological fracture (distal location) through an extremely large renal cell carcinoma of the left pelvis. There is a large soft tissue component extending almost to the midline.  
C. Solitary renal cell carcinoma metastasis of the right proximal femur extending into the pelvis. This MRI shows a large extraosseous component with complete destruction of the periacetabular area, and with tumor filling the ischiorectal space. Solitary renal cell carcinoma metastasis is considered to be one of the few indications for radical amputation due to metastatic carcinoma. (continued)
structures because of contralateral blood flow and rich anastomotic vessels; however, it will significantly devascularize the gluteus maximus muscle. Classic hemipelvectomy, in which these branches are divided, has a substantial rate of wound complications as a direct result.

**Pelvic Viscera**
- In addition to the critical vascular structures, major organs of the gastrointestinal and genitourinary tracts are present and exposed during a hemipelvectomy. These structures should be completely evaluated before surgery.
- The bladder and urethra, and the prostate in male patients, are located above and under the pubic symphysis. Placement of a Foley catheter with a large inflated balloon makes these structures easier to palpate during surgery. Care must be taken not to injure the urethra during division of the symphysis. In addition, the venous plexus surrounding the prostate can be a significant source of bleeding that can be difficult to control even with good visualization of the organ. The ureters are at risk of injury as they cross over the iliac vessels from lateral to medial. The peristaltic motion of the ureters helps to identify these structures.
- In female patients the ovaries, fallopian tubes, uterus, cervix, and vagina require identification and protection. Care in taking a complete history of the patient will identify women who have undergone hysterectomies. In female patients who have not undergone such surgery, these organs are found under and adjacent to the bladder. They can be easily and safely retracted out of the operative field.

- Most of the gastrointestinal tract is protected by the peritoneum and is gently retracted out of the operative field. Of particular concern is the sigmoid colon, which must be protected during left-sided amputations. The colon and rectum must also be identified and protected during the division of the sling muscles before completing the amputation. Insertion of a rectal tube before surgery helps to identify both these structures and to decompress them. Because of the possibility of bacterial contamination from these structures, preoperative bowel preparation and the use of appropriate antibiotics are prudent.

**INDICATIONS**

**Unresponsive Sarcomas Involving Multiple Compartments**
- The most common indication for hemipelvectomy is a non-metastatic sarcoma that fails to respond to neoadjuvant chemotherapy or radiation. In addition, patients with extremely large sarcomas involving multiple compartments of the thigh may require an immediate amputation to avoid tumor fungation, hemorrhage, and secondary infection. In each case the type of hemipelvectomy performed is dictated by the anatomic location of the tumor and the expected defect to be created by the resection.
- For example, a posterior tumor involving the buttock and sciatic nerve that cannot be resected by a buttockectomy can be removed and closed with a vascularized pedicle anterior flap hemipelvectomy.
Contamination of Surrounding Structures

- Patients with extensive contamination of compartments from inappropriately placed biopsies or from unplanned intralesional resections of sarcomas around the pelvis, hip, and proximal thigh are candidates for hemipelvectomy. In addition, pathologic fractures of the proximal femur often contaminate unexpectedly large volumes of tissue (Fig 2).
- Traditionally, such fractures have been treated with hemipelvectomy, although some institutions now attempt limb-sparing procedures after aggressive preoperative (neoadjuvant) treatment and spica immobilization.

Nonviable Extremity Precluding Limb Salvage

- Elderly patients with significant peripheral vascular disease and patients with fungating, infected sarcomas that preclude limb-sparing surgery may be candidates for hemipelvectomy.
- Conversely, very young and skeletally immature children with primary sarcomas who are not suitable candidates for limb-sparing procedures because of the inevitable problem of limb-length discrepancy may be treated with hemipelvectomy.
- Typically, the youngest patients adapt most completely to their missing limb and lead extremely active lives. Psychological counseling for the parents and family is essential under such circumstances.

Failure of Previous Resection

- Hemipelvectomy is indicated as a final salvage procedure for patients with local recurrence in the thigh or buttock after aggressive surgical and medical treatment.
- Careful patient evaluation is necessary to rule out metastatic disease in such cases.
- Hemipelvectomy may also be required to control infection after limb-sparing procedures around the hip and pelvis.

Palliation

- The use of radical amputation for palliation of patients with metastatic disease is rare. Palliative indications for hemipelvectomy include uncontrollable pain from tumor involvement of the lumbosacral plexus, sciatic, and femoral nerves.
- Patients with uncontrollable local disease from metastatic carcinoma who have failed to respond to all conventional treatments, including radiation and chemotherapy, may also benefit from amputation.
- Realistic expectations and psychological support for the patient and family are essential in such cases.

Nononcologic Indications

- Modified or anterior flap hemipelvectomy may be required for uncontrolled decubiti and osteomyelitis of the hip and pelvis in patients with longstanding paralytic conditions. Both function and emotional well-being often improve rapidly after the source of chronic sepsis has been surgically removed.
- For patients with partial pelvic amputation and open hemorrhaging fractures of the pelvis, emergency hemipelvectomy may be life-saving. In both circumstances, oncologic margins are not required, making the surgery easier to perform.

IMAGING AND OTHER STAGING STUDIES

- Complete imaging and staging of the patient are essential for proper patient selection and preoperative planning. Routine preoperative staging studies of the patient should include a computed tomography (CT) scan of the chest and a total body bone scan to detect metastatic disease.
- Images of the liver and abdomen may be indicated for patients with certain tumors, such as myxoid liposarcomas that can present with unusual sites of metastases.

Standard Radiographs

- Radiographs remain the gold standard for the detection and diagnosis of bone sarcomas. Evaluation of patients with suspected pelvic and hip or thigh tumors should always include a standard anteroposterior (AP) pelvis view that extends from the top of the iliac crests to below the pubic symphysis.
- Additional views of the pelvis may be helpful, including the iliac and obturator oblique views described by Judet, as well as inlet and outlet views. Given the complexity of pelvic anatomy, cross-sectional images are vital.

CT and Magnetic Resonance Imaging

- CT and magnetic resonance imaging (MRI) both provide the ability to image pelvic anatomy in cross-sectional planes. MRI provides better images in the sagittal and coronal planes. Use of oral, intravenous, and rectal contrast media can greatly improve the ability of CT scanning to image the visceral organs of the pelvis.
- CT is extremely useful in evaluating the sacroiliac joint, the sciatic notch, and the symphysis pubis.
- MRI often provides a better image of the soft tissue and the intramedullary extent of sarcoma. The retroperitoneal lymph nodes can be evaluated with either technique.
- Because of the complementary nature of the information provided by these scans, a complete evaluation may require both imaging modalities.

Angiography

- Preoperative angiography of the pelvis is extremely useful in delineating the relationship of the iliac branches to the tumor. Older patients undergoing anterior flap hemipelvectomy may have silent atherosclerotic disease of the femoral vessels that could jeopardize the success of the flap.
- If a modified hemipelvectomy is being considered, angiography reveals the level of the common iliac bifurcation. Patients undergoing palliative amputation may benefit from preoperative embolization to reduce intraoperative bleeding.

Venography and Other Tests

- Complete evaluation of the visceral structures of the pelvis may require additional studies. Dedicated radiographic evaluation using contrast materials of the colon, rectum, bladder, urethra, and uterus is useful if tumor involvement is suspected. Direct visual inspection by sigmoidoscopy and cystoscopy may be essential in selected patients. Pelvic venography should be performed if there is any clinical suspicion of venous obstruction (ie, distal edema). Venous tumor thrombi often occur with large pelvic chondrosarcomas. Tumor thrombi should be removed during surgery.

Biopsy

- The biopsy of tumors around the pelvis and proximal femur must be extremely well planned to avoid contaminating the
posterior flap, which is the most common type of hemipelvectomy performed. The orthopedic oncologist who will be performing the amputation should be present during the biopsy procedure to ensure that a proper and appropriately placed biopsy is performed (FIG 3).

SURGICAL MANAGEMENT

Positioning

- The patient is placed in a modified semisupine position. Incision of the abdominal wall and retroperitoneal dissection of the iliac vessels are performed first. The common iliac, external iliac, or internal iliac (hypogastric) vessels are selectively ligated according to the type of hemipelvectomy to be performed.

Approach

- Exposure of the pubis, bladder neck, and urethra permits sectioning of the symphysis pubis. The iliac wing, sacroiliac joint, or sacrum is then exposed and divided to complete the amputation. Division of the lumbosacral plexus at the level of the sacrum or pelvis is accomplished at the same time. A fasciocutaneous or a myocutaneous flap (involving the gluteus maximus for posterior flaps or the anterior compartment of the thigh for anterior flaps) is then completed. Flexion and adduction and abduction of the hip then allows the surgeon to divide the muscles and ligaments of the pelvic floor and complete the amputation.

- The classic posterior flap hemipelvectomy can be visualized as consisting of five major surgical components.

ANTERIOR RETROPERITONEAL APPROACH THROUGH THE ILIOINGUINAL INCISION

- Through this incision (TECH FIG 1A), the retroperitoneal space is explored by detaching the abdominal wall musculature from above the ilioinguinal ligament and off the iliac crest (TECH FIG 1B). For large tumors of the ilium the retroperitoneal space is entered laterally, where there is more free retroperitoneal fat. The peritoneum is then reflected off the tumor mass and the retroperitoneal space is developed. The ureter remains on the peritoneal reflection. The iliac arteries or hypogastric vessels are ligated and transected, the psoas muscle and the femoral nerve are transected, and the abdominal wall is released from the iliac crest to the posterior superior iliac spine. All structures are transected or mobilized anteriorly before proceeding to the next steps. It is crucial to identify all of the vascular struc-
B. The retroperitoneal space is easily entered by detaching the abdominal wall musculature from above the ilioinguinal ligament and off the iliac crest. The peritoneum is then reflected off the tumor mass, and the retroperitoneal space is developed. It is crucial to identify all of the vascular structures initially to prevent any mistakes in ligation. C. A modified hemipelvectomy is an amputation preserving a portion of the wing of the ilium and the underlying gluteus maximus muscle and its major pedicle the inferior gluteal vessels.

The second major step is the perineal incision. This incision extends from the symphysis pubis down to the ischium along the inferior pubic ramus. The ischiorectal space is exposed along the inferior pubic ramus to the symphysis pubis. The symphysis pubis is disarticulated. The bladder is retracted with a malleable retractor, and an additional small malleable retractor is placed beneath the symphysis pubis notch to protect the urethra. The urethra is easily palpable and protected with a malleable retractor (TECH FIG 2). A foley catheter is in place. For large tumors of the pelvic floor the urethra may be around the pseudocapsule of the tumor. Therefore, great care must be taken not to enter the tumor or the pericapsular structures of the prostate.

TECH FIG 2 • The perineal incision is then begun prior to abducting or flexing the affected extremity. The symphysis pubis is opened with a small osteotome or a cutting cautery.
POSTERIOR FLAP RETROGLUTEAL AREA EXPLORATION

- The third component of the procedure is the posterior fasciocutaneous or subcutaneous flap that is mobilized along the iliotibial band and the greater trochanter toward the sacroiliac joint. A classic hemipelvectomy involves the removal of all gluteal structures, and only the subcutaneous flap remains (TECH FIG 3). A classic hemipelvectomy consists of a disarticulation of the sacroiliac joint, therefore requiring all of the abdominal muscles to be released up to the paraspinal muscles. The iliolumbar ligament is a good surgical landmark: it inserts onto the ilium posteriorly just above the superior aspect of the sacroiliac joint. This is especially useful in obese patients in whom the sacroiliac joint cannot easily be palpated.

TECH FIG 3 • A. The abdominal wall musculature is released from the crest of the ilium with a 1–2 cm cuff of muscle remaining along the ilium. B. The psoas muscle has a tendency to bleed postoperatively and should therefore be oversewn. Depending on the type of hemipelvectomy to be performed (classical or modified), the level of the abdominal wall musculature release and the level of the posterior osteotomy will vary.

DETACHMENT OF PELVIC FLOOR MUSCULATURE

- This maneuver is performed with the hip abducted and flexed, with the surgeon standing between the two extremities, facing the pelvis. While the assistant abducts the extremity, the pelvic floor musculature is stretched and ligated through Kelly clamps, beginning at the pubic ramus and ending at the sacroiliac joint (TECH FIG 4).

TECH FIG 4 • A. Completion of amputation and release of pelvic floor muscles. The final steps of the amputation involve the release of the sacroiliac joint and the remaining pelvic sling muscles attaching to the ilium and pelvic floor. (continued)
**COMPLETION OF THE AMPUTATION WITH SACROILIAC DISARTICULATION**

- The amputation is completed by transecting the sacroiliac joint with a large osteotome while retracting the peritoneal contents and avoiding the previously transected iliac vessels. The surgical assistant stands on the same side of the table as the surgeon and flexes and abducts the lower extremity to expose the pelvic floor muscles for the surgeon. A sponge on a stick is used to push the rectum off the pelvic sling muscles in the inferior portion of the wound. If a left-sided hemipelvectomy is performed, great care must be taken to mobilize the rectum to avoid injuring it. The sling muscles are clamped with Kelly clamps and transected. The anterior capsule of the sacroiliac joint and occasionally some of the sacrolumbar trunks are the only remaining structures that must be opened and released. The sacroiliac joint is not opened previously due to the potential for bleeding from injury to the perisacral veins.

- If a posterior modified hemipelvectomy is performed, the wing of the ilium is transected from the sciatic notch to the midportion of the ilium. The hypogastric artery is preserved and the external iliac artery is ligated. The choice between a classic hemipelvectomy and a modified posterior flap hemipelvectomy is made preoperatively. In general, modified hemipelvectomies are performed for thigh and groin lesions, whereas classic hemipelvectomy are performed for true pelvic tumors of the muscle or bony structures (TECH FIG 5A).

- A modified hemipelvectomy preserves a portion of the wing of the ilium and the underlying gluteus maximus muscle and its major pedicle, the inferior gluteal vessels. Therefore, an osteotomy is performed through the wing of the ilium starting at the sciatic notch. The iliacus muscle is transected internally and the abductor muscles are transected longitudinally (posteriorly). All of the muscles located anteriorly in the pelvis are transected at this step.

---

**TECH FIG 4** (Continued) **B.** Gross specimen following hemipelvectomy for multiple recurrences of metastatic renal cell carcinoma. Small arrows indicate recurrent tumor; large arrows indicate intramedullary tract site. **C.** This tumor has crossed several anatomical boundaries and involves the anterior, posterior, and medial compartments of the thigh. Large arrow indicates the location of the femur; small arrows indicate intervascular septa. (Courtesy of Martin M. Malawer.)

**TECH FIG 5** **A.** Variation of a posterior flap for a modified posterior flap hemipelvectomy. A modified posterior flap hemipelvectomy is an amputation through the wing of the ilium with preservation of the gluteus maximus and its major pedicle and the inferior gluteus vessels. (continued)
The sacroiliac joint is also identified anteriorly and the vessels are mobilized off the sacroiliac joint in preparation for the sacroiliac disarticulation that is the final step of the operative procedure.

- Closure of the flap is then performed over large 28-gauge chest tubes with suction drainage (TECH FIG 5B).

Marcaine epineural catheters are used for continuous pain relief postoperatively (TECH FIG 5C). Two catheters are used: one is inserted into the lumbosacral plexus and the other into the femoral nerve.

The wound is closed by rotating and suturing the prepared myocutaneous flap to the abdominal wall and flank.

PEARLS AND PITFALLS

Preoperative

- Minimizing the morbidity and mortality associated with hemipelvectomy requires careful physical and psychological preparation of the patient. Patients receiving preoperative chemotherapy or radiation therapy require time to recover from their neutropenia and anemia. Use of supportive growth factors such as erythropoietin and granulocyte colony-stimulating factor may be of significant benefit. Replacing red cell mass by blood transfusion and correcting bleeding abnormalities are essential to reduce the risk of intraoperative mortality.

- Patients with poor nutrition secondary to disease and the nausea and vomiting induced by chemotherapy may require hyperalimentation before and after surgery to reduce problems with wound healing.

Intraoperative

- To reduce the risk of postoperative infection, bowel preparation should be performed for all patients.

- Perioperative antibiotic coverage for aerobic skin flora and anaerobic bowel flora is required.

- If the tumor encases or involves the major vessels, extensive bleeding should be anticipated. Extensive blood loss and replacement in excess of one to two times the patient’s circulatory volume may create life-threatening coagulopathies and pulmonary complications.

- Intraoperative retraction of the peritoneum and use of postoperative narcotics contribute to the development of an ileus that may last for a week or more.

Postoperative

- Postoperative care to prevent hematomas and seromas includes the use of large-bore suction drains and pressure dressings using Ace wraps. A Foley catheter and a nasogastric tube are used to prevent abdominal distention; this reduces pressure on the skin closure. Skin sutures or staples should be retained for 3 to 4 weeks to minimize the risk of wound dehiscence.

- Routine placement of a nasogastric tube and avoidance of oral feeding are required to prevent nausea, vomiting, aspiration, abdominal distention, and wound complications. Early intravenous nutritional supplementation should be considered.

- Patients undergoing hemipelvectomy face a unique combination of psychological stress related to the loss of limb and potential loss of life from the underlying disease. Ongoing psychological support for the patient and family is essential.
POSTOPERATIVE CARE

- The patient should understand that phantom limb sensations are to be expected and that they can be treated with analgesics. The discomfort will lessen over time.
- Although successful rehabilitation depends to a great extent on the patient’s attitude, the physiatrist can help tremendously in these efforts. A positive attitude toward functional recovery augmented by early postoperative ambulation may move the patient rapidly to his or her goals. A positive approach is amplified by contact with other patients who have met some of the rehabilitation challenges. This can provide an immeasurable psychological boost to the patient. The oncologist, rehabilitation therapist, and others involved in the postoperative care must coordinate their efforts carefully.

OUTCOMES

- Most patients can ambulate after appropriate rehabilitation and use of hemipelvectomy prostheses.
- Most patients who survive their disease will go on to enjoy a high quality of life and participate in a multitude of recreational activities (FIG 4).
- Recent reports of series of hemipelvectomy patients have shown that this procedure has a low mortality rate and offers an acceptable survival in carefully selected patients.
- Quality-of-life studies suggest that long-term morbidity in patients who have undergone this radical amputation is not greater than that experienced by patients who have undergone other cancer treatments.
- Elderly and overweight patients may become wheelchair-dependent after this procedure because of the increased workload required to ambulate. Some children and adults find that a prosthesis slows their ability to ambulate with crutches. However, a prosthesis enables the wearer to stand for prolonged periods of time without supports and frees both hands for other activities.

COMPLICATIONS

- All patients undergoing hemipelvectomy will have considerable phantom limb sensation. It may be a more disruptive long-term problem to the patient than the loss of the limb itself. Patient education, aggressive medical treatment, and rigorous physical rehabilitation play a role in minimizing the impact of these sensations. Injection and infusion of local anesthetics into the lumbosacral plexus and stumps of the sciatic and femoral nerves may significantly reduce actual pain and phantom sensation in the immediate postoperative period.
- Another serious postoperative complication is wound necrosis. Ligation of the common iliac vessels during a classic posterior flap hemipelvectomy deprives the flap of its major blood supply; 10% to 50% of patients develop clinically significant ischemia. Pressure from prolonged lying or sitting on the flap may result in ischemic necrosis. Early identification of necrosis...
and surgical revision is essential to minimize additional complications. Meticulous attention to preserving the fasciocutaneous vessels and a portion of the gluteus maximus can reduce the incidence of ischemic necrosis.

- All patients undergoing hemipelvectomy have significant risk factors for infection, such as tumor-related catabolism, chronic malnutrition, and chemotherapy-induced anemia and neutropenia. As a result, it is not surprising that infection is seen in about 15% of patients. Other factors that increase the risk of infection include immunosuppression from surgical stress, transfusions, and psychological depression. Steps to reduce the incidence of infection should include the use of preoperative bowel preparation, use of a purse-string suture to close the anus during surgery, broad-spectrum perioperative antibiotic coverage, and the use of large-bore closed suction drains to prevent retroperitoneal hematomas. Infection may significantly retard wound healing; aggressive surgical débridement and prolonged dressing changes are often necessary.

REFERENCES

BACKGROUND

- The anterior flap hemipelvectomy is a modified version of the classic posterior flap hemipelvectomy. Instead of using the traditional posterior skin flap of the gluteal region, a myocutaneous flap from the anterior thigh is used to close the peritoneum after amputation through the sacroiliac joint and the pubic symphysis. This modification has permitted the treatment of difficult buttock and pelvic tumors where the posterior flap was involved or contaminated by tumor.
- Patients with extensive soft tissue sarcomas of the buttock or bone sarcomas of the pelvis that extend posteriorly, once thought to be incurable by standard posterior flap hemipelvectomy, can often be treated with an anterior flap hemipelvectomy.
- The procedure, which originally entailed use of an anterior skin flap raised off a portion of the superficial femoral vessels, was modified to include a full-thickness myocutaneous flap raised from the anterior thigh.
- The major advantage of anterior flap hemipelvectomy is the creation of a large vascularized myocutaneous flap that is ideal for closure of significant posterior defects (FIG 1). As much of the anterior thigh compartment may be saved as needed, depending on the size of the defect being closed. As always, careful patient selection is critical in ensuring that an acceptable outcome is achieved. For example, elderly patients and diabetics with silent atherosclerotic disease of femoral vessels must be carefully evaluated with preoperative angiography.
- The hemipelvectomy procedures described in Chapter ON-21 required a flap of buttock skin to cover the surgical defect. Anterior flap hemipelvectomy allows sacrifice of the entire buttock and all the overlying skin and soft tissue to the midline. Even patients who have a tumor-contaminated buttock to the midline may have a potentially curative procedure.
- If possible, tumors in this area, especially those of low histologic grade, should be treated with an excision of the gluteus maximus muscle (buttckectomy). However, if tumor extends through the gluteus maximus muscle to involve the gluteus medius or minimus, if tumor encases the sciatic nerve, or if tumor is directly adjacent to the pelvic bones, a radical amputation using an anterior myocutaneous flap is indicated.

ANATOMY

- The surgeon must be familiar with the pelvic anatomy as well as the thigh musculature and femoral vessels. The anatomic key to this procedure is the major vascular pedicle of the pelvis and extremity. Oncologic considerations for tumor involvement of the bone or soft tissues in the pelvis are identical to those discussed in Chapter ON-21 on posterior flap hemipelvectomy.
- The external iliac vessels leave the pelvis and cross through the femoral triangle, where they become the common femoral vessels. A single branch supplying the iliac crest may be encountered along the medial aspect of the external iliac vessel just below the inguinal ligament. The superficial femoral vessels travel underneath the sartorius muscle along most of the length of the thigh; they pass through the adductor hiatus and become the popliteal vessels behind the knee. The major branch in the femoral triangle is the profunda femoris, which arises from the posterior aspect of the superficial femoral vessel and passes deep to the posterior surface of the femur. Ligation of the profunda femoris is required to elevate the anterior flap. The common femoral and superficial femoral vessels are preserved.
- The (four) quadriceps muscles, the adductor muscles, and the sartorius muscle all have a vascular supply that arises from pedicles off the superficial femoral artery. Perforating branches from the profunda are present in the vastus lateralis and may be encountered as they pass through the intramuscular septum.
- The entire anterior and medial compartments can be elevated off the femur by dividing the quadriceps tendon above the patella and peeling the full-thickness myocutaneous flap off the anterior femoral periosteum. To prevent hemorrhage, care must be taken to properly ligate all perforating vessels, as well as the superficial femoral vessels, at the level of the adductor hiatus.
- Division of the skin at the inguinal canal and skeletonization of the external iliac vessels permit the entire flap to be rotated as necessary to cover the defect created by the amputation.
- Use of this flap for closure results in improved cosmesis and facilitates fitting of a prosthesis for an improved functional result. In addition, this flap permits radiation therapy to the remaining pelvis without any wound complications. The nature of the flap available for closure permits greater posterior resection than that possible during a traditional posterior flap hemipelvectomy.
- The entire buttock compartment (ie, the gluteal muscles, sciatic nerve, sacrospinous ligaments, and sacral alar) can be safely removed.
- The anterior myocutaneous flap consists of a portion of or the entire quadriceps muscle group on its vascular pedicle, the superficial femoral artery. This flap covers the entire peritoneal surface and generally heals with minimal problems.

IMAGING AND OTHER STAGING STUDIES

- In addition to the routine radiographic evaluation of the pelvis (radiographs, computed tomography [CT; FIG 2] and magnetic resonance imaging [MRI] scans, and bone scans) necessary to determine the patient’s suitability for a hemipelvectomy, angiography of the femoral vessels is essential for patients undergoing anterior flap hemipelvectomy.
- The variable nature of the profunda femoris, as well as the frequent presence of silent atherosclerosis of the superficial femoral artery in elderly patients or in patients with a history of smoking, can greatly affect the outcome of this procedure. In addition, visualization of the pelvic vessels can help to ensure that they are not involved with the tumor.
- CT and MRI are required to determine whether the tumor involves the sacrum or the vertebra. Spinal involvement is a contraindication to this procedure (Fig 2).
Chapter 22  ANTERIOR FLAP HEMIPELVECTOMY

INDICATIONS

- Anterior flap hemipelvectomy is indicated for tumors involving the buttock that cannot be resected with a less radical procedure. Patients who have failed to respond to prior attempts at limb-sparing surgery, with or without radiation, or who have tumors that primarily involve the posterior thigh and sciatic nerve are also candidates for this procedure.
- This procedure may also be indicated after failed attempts at limb-sparing surgery, as well as for patients with nononcologic indications for amputation (eg, uncontrollable sepsis from sacral or trochanteric osteomyelitis).
- Nononcologic indications include selected paraplegics with uncontrollable chronic osteomyelitis of the pelvis or hip joint.

SURGICAL MANAGEMENT

Preoperative Planning

- Careful presurgical planning is necessary to achieve optimal results. The planned surgical incision is drawn before any cut-
- The planned surgical incision is drawn before any cut-
- The planned surgical incision is drawn before any cut-
- The planned surgical incision is drawn before any cut-

Positioning

- After being placed supine on the operating table, the patient is rolled into the lateral position, with the iliac crest at the flexion point of the table. As the patient is positioned, a cushion is placed beneath the iliac crest and greater trochanter to prevent pressure necrosis of the skin. Padding beneath the axilla is used to allow full excursion of the chest wall and to prevent injury to the brachial plexus.
- The arm is placed on a Krasky arm rest. An elastic wrapping or a support stocking is used to prevent blood from pooling in the contralateral lower extremity.
- The operating room table is flexed to open the angle between the crest of the ilium and the lumbar vertebrae.
- The anus is sutured shut.
- The lower extremity is prepared and draped free, with the skin exposed circumferentially from the knee to the iliac crest.

FIG 1 • Clinical photograph showing a sarcoma recurrence in the posterior thigh with local tumor fungation after surgery and radiation therapy. The old posterior incision is visible (arrow). This is a classic indication for an anterior flap hemipelvectomy, which is used instead of the classic posterior flap hemipelvectomy. (Courtesy of Martin M. Malawer.)

FIG 2 • CT scan showing a large extraosseous chondrosarcoma of the buttock (Tu) with a thin rim of gluteus maximus muscle remaining (G). There is early intrapelvic extension through the sciatic notch. (Courtesy of Martin M. Malawer.)

FIG 3 • Clinical photograph of anterior flap drawn before surgery. The anterior myocutaneous flap consists of a large portion of the anterior thigh skin, subcutaneous tissue, and underlying quadriceps muscle. This flap is based on the common femoral and superficial femoral artery. The profundus artery is ligated when raising this flap. The incision extends along the medial aspect of the thigh below the sartorius so that the superficial femoral artery can be identified and ligated distally to preserve adequate vascularity to the quadriceps. The transverse incision is performed several inches above the knee. B. The posterior incision outlined extends from the anterior flap and follows the sacroiliac joint down to the gluteal crease. It then travels transverse posteriorly to meet the anterior flap. This incision avoids any contamination of the posterior incision. This procedure was developed by Dr. Paul H. Sugarbaker at the National Cancer Institute during the 1980s. C. Intraoperative photograph showing a large myocutaneous quadriceps flap elevated off the femur as the first operative stage during an anterior flap hemipelvectomy. The profundus femoris artery is ligated so that the flap can be raised above the inguinal ligament and the retroperitoneal approach of the hemipelvectomy can proceed. (Courtesy of Martin M. Malawer.)
ANTERIOR AND POSTERIOR SKIN INCISIONS

- Before the operation, the surgeon must ensure that the myocutaneous flap created from the tissue overlying the quadriceps muscle will cover the operative defect created in the buttock. The location of the proposed incision is mapped out with a marking pen and the width and length of the flap are compared with the anticipated defect in the buttock. Once it is ascertained that the flap is adequate to cover the defect, the remainder of the incision is determined (TECH FIG 1).

- First, the location of the incision is drawn medial to the tumor at or near the midline posteriorly above the anus. Superiorly and laterally the incision should parallel the wing of the ilium to the anterior superior iliac spine. It then continues distally along the midpoint of the lateral aspect of the thigh to the junction of the lower and middle thirds of the thigh.

- The medial incision courses 2 to 3 cm lateral to the anus, then anteriorly in the gluteal crease toward the pubic tubercle. It continues along the midpoint of the thigh to the junction of the lower and middle thirds of the thigh.

- The two longitudinal incisions extending along the lateral and medial aspects of the thigh are connected by a transverse incision over the anterior aspect of the thigh. The location of this transverse incision determines the length of the myocutaneous flap. Hence, the transverse incision is positioned so the tip of the flap will extend to the level of the iliac crest.

POSTERIOR DISSECTION IN THE ISCHIORECTAL SPACE

- In excision of buttock tumors, the medial margin of the tumor is usually the closest one to the line of excision. Therefore, the dissection should commence medial to the tumor to allow the surgeon to assess operability before completion of the amputation is required (TECH FIG 2).

- The initial incision is made superficial to the sacrum in the midline, through fascia to the midsacral spines. A cuff of skin 2 to 3 cm long is preserved around the anus.

- The sacral attachments of the gluteus maximus and erector spinae muscles are divided from their origins between the midsacral spines and the dorsal sacral foramina. Biopsies from the medial margin of resection are secured. By removing the outer table from the sacrum, biopsies from sacral nerves may also be obtained if indicated. If by cryostat sectioning and histologic examination these biopsies are negative, the amputation may proceed.
Chapter 22  
ANTERIOR FLAP HEMIPELVECTOMY

**LATERAL INCISION OF THE MYOCUTANEOUS FLAP**
- Abdominal and back muscles that arise on the sacrum and the iliac crest are incised in the plane of attachment of muscle to bone to minimize blood loss. Muscles to be cut include the external oblique, erector spinae, latisimus dorsi, and quadratus lumborum (TECH FIG 3).

**TRANSECTION OF THE SUPERFICIAL FEMORAL ARTERY**
- The extremity is flexed at the hip to place the tissues in the area of the gluteal crease under tension. The perianal incision is extended toward the pubic tubercle along the gluteal crease. The deep dissection is continued lateral to the rectum into the ischiorectal fossa. The remaining origins of the gluteus maximus muscle are now severed from the coccyx and sacrotuberous ligament (TECH FIG 4).

**RELEASE OF THE VASTUS LATERALIS**
- The surgeon now moves from the posterior to the anterior aspect of the patient. The anterior incision at the junction of the middle and lower thirds of the thigh is made and continued down to the femur, transecting the entire quadriceps muscle (TECH FIG 5).
- Laterally, this incision is continued superiorly toward the greater trochanter to the anterior superior iliac spine. The tensor fascia lata muscle is separated from its investing fascia so that it is included with the specimen.

---

**TECH FIG 3** - Release of the back muscles of the iliac crest. (Courtesy of Martin M. Malawer.)

**TECH FIG 4** - Posterior dissection in the ischiorectal space. (Courtesy of Martin M. Malawer.)

**TECH FIG 5** - Lateral incision of the myocutaneous flap. (Courtesy of Martin M. Malawer.)
TRANSECTION OF THE SUPERFICIAL FEMORAL ARTERY

- The fascial covering of the vastus lateralis of the quadriceps femoris muscle is dissected free of the flexor muscles and traced to its insertion on the femur. Then the vastus lateralis is severed from the femur using electrocautery. In performing the dissection from this point on, care must be taken not to separate muscle bundles of the myocutaneous flap from the overlying skin and subcutaneous tissue (TECH FIG 6).

TECH FIG 6 • Release of the vastus lateralis from the femur. (Courtesy of Martin M. Malawer.)

RELEASE OF THE QUADRICEPS MUSCLE FROM THE FEMUR

- The medial skin incision is from the area of Hunter’s canal to the pubic tubercle. The superficial femoral vessels are located at their point of entry into the abductor muscles and are ligated and divided at this level. These vessels course along the deep margin of the myocutaneous flap, and in the subsequent dissection they are traced superiorly to the inguinal ligament. Multiple small branches from the superficial femoral vessels to the abductor muscles must be clamped, divided, and ligated (TECH FIG 7).

TECH FIG 7 • Transection of superficial femoral artery. (Courtesy of Martin M. Malawer.)

RELEASE OF THE MYOCUTANEOUS FLAP FROM THE FEMUR

- Vigorous upward traction on the myocutaneous flap allows the origins of the vastus intermedius and the vastus medialis to be severed from the femur. As the release of the myocutaneous flap continues up toward the pelvis, the profunda femoris vessels are identified. These vessels are ligated and divided at their origin from the common femoral artery (TECH FIG 8).
- The myocutaneous flap is freed from its pelvic attachments by the following procedure. The abdominal muscles and fascia are severed from the iliac crest. The sartorius muscle is transected at its origin on the anterior superior iliac spine. The rectus femoris is transected at its origin on the anterior inferior iliac spine. The femoral sheath overlying the hip joint is divided. The left rectus abdominis muscle is released from the pubic bone.
- By retracting the myocutaneous flap medially, full access to the pelvis is achieved. Blunt dissection along the femoral nerve allows rapid dissection into the pelvis to expose the vessels and nerves to be transected in the subsequent phases of the procedure.
DIVISION OF THE SYMPHYSIS PUBIS

To divide the symphysis pubis, the bladder and urethra are protected and a scalpel is used to locate and divide the cartilaginous joint (TECH FIG 9).

TRANSECTION OF THE ILIAC VESSELS

- The internal iliac artery and vein are divided at their point of origin from the common iliac vessels. Multiple visceral branches of the internal iliac vessels are divided in their course superficial to the sacral nerve roots. Strong medial traction on the viscera will help expose these vessels. When this phase of the dissection is completed, the nerve roots should be clearly visualized throughout their course in the pelvis (TECH FIG 10).
- The common iliac lymph nodes remain with the patient in this procedure, in contrast to a standard hemipelvectomy, in which they are removed.
DIVISION OF THE PSOAS MUSCLES AND NERVE ROOTS

- The psoas muscle is divided near its junction with the ili-acus muscle. The obturator nerve deep to the muscle is also divided. Care is taken to preserve the femoral nerve coursing into the myocutaneous flap. The lumbosacral and sacral nerve roots are ligated and divided close to the ventral sacral foramina (Tech Fig 11).

TECH FIG 11 • Division of the psoas muscle and nerve roots. (Courtesy of Martin M. Malawer.)

DIVISION OF THE PELVIC DIAPHRAGM AND SACRUM

- The leg is elevated to place under tension the individual muscles that constitute the pelvic diaphragm. Care is taken to protect the urethra, bladder, and rectum. The urogenital diaphragm, levator, and piriformis muscles are divided. These muscles are transected near their pelvic attachments (Tech Fig 12).
- The surgeon should again change orientation and move back to the posterior aspect of the patient. Using an osteotome and commencing at the tip of the coccyx, the coccyx and sacrum are divided in a plane that bisects the sacral foramina.
  - Initially, the course of the osteotome should parallel the midsacral spines. The surgeon, being posterior to the patient, reaches around the coccyx with the left hand to locate the S5 neural foramina from within the sacrum. This is at the junction of the sacrum and the coccyx. By holding the osteotome with the right hand, the direction for bone transection can be precisely determined. The assistant drives the osteotome through the bone with the mallet.
  - At the upper portion of the sacrum, care must be taken not to fracture inadvertently through the bone. The lumbosacral ligament is divided to release the specimen.

Chapter 22  ANTERIOR FLAP HEMIPELVECTOMY

TECHNIQUES

PEARLS AND PITFALLS

Closure

- Sugarbaker and others have shown the utility of a myocutaneous pedicle flap based on the femoral vessels and anterior compartment of the thigh for closure of the wound in patients with tumors involving the posterior buttock structures.
- The primary advantage of this procedure is that the anterior flap raised from the thigh can be used to reconstruct an enormous posterior defect with little risk of flap necrosis. Patients who are expected to require substantial doses of radiation postoperatively should be considered for this procedure whenever possible, since the well-vascularized myocutaneous flap tolerates radiation well.
- Great care must be taken not to dissect or shear the subcutaneous tissue and skin overlying the quadriceps during the creation of the flap, because this will compromise the cutaneous circulation.
- Occasionally, tumor tissue or heavily irradiated skin overlying the superficial femoral artery may require sacrifice of the skin pedicle. In this instance the island myocutaneous flap should be used.

POSTOPERATIVE CARE

- The patient should understand that phantom limb sensations are to be expected and that they can be treated with analgesics. The discomft will lessen over time.
- Although successful rehabilitation depends to a great extent on the patient’s attitude, the physiatrist can help tremendously in these efforts. A positive attitude toward functional recovery augmented by early postoperative ambulation may move the patient rapidly to his or her goals. A positive approach is amplified by contact with other patients who have met some of the rehabilitation challenges. This can provide an immeasurable psychological boost to the patient. The oncologist, rehabilitation therapist, and others involved in the postoperative care must coordinate their efforts carefully.

OUTCOMES

- The potential for rehabilitation with this procedure is excellent. Patients who are free of disease use a prosthesis regularly. Patients walk with the prosthesis without the use of crutches or a cane.
- Because of the vascular nature of this flap, the surgical wound heals rapidly in the vast majority of patients. Accordingly, the 10% to 30% risk of ischemic necrosis associated with posterior flap hemipelvectomy is not seen with an anterior flap procedure. Likewise, the risk of infection in the postoperative period is markedly reduced.
- Rehabilitative considerations and the risk of phantom pain are similar to those associated with other types of hemipelvec-

REFERENCES

BACKGROUND

- Hip disarticulation is an amputation of the lower extremity through the hip joint capsule. Although most tumors of the lower extremities are amenable to limb-sparing techniques, some tumors of the femur and thigh are so extensive that hip disarticulation is needed for adequate tumor resection.
- With advances in prosthetic design, patients can ambulate with a prosthesis despite the larger energy expenditure needed to ambulate after a hip disarticulation compared to more distal amputations. Even without prosthetic use, most patients are very successful in ambulating and carrying out daily activities.
- Performing a hip disarticulation may be more preferable in some cases instead of leaving a patient with a very short above-knee amputation stump site, which can make prosthesis fitting difficult.

ANATOMY

- The hip joint region is supplied by several major arteries. Familiarity with these structures can minimize intraoperative bleeding if they can be identified and ligated as needed. These arteries include the profunda artery, the medial and lateral circumflex arteries, and the obturator and superior and inferior gluteal arteries.
- The tensor fascia lata, gluteus maximus, and iliotibial band form an outer muscular envelope around the hip, and at least one of these structures usually needs to be split to gain access to the hip.
- The femoral triangle must be identified to access the main neurovascular structures encountered in this procedure. The femoral triangle is bordered superiorly by the inguinal ligament, laterally by the sartorius muscle, and medially by the adductor longus muscle.
- Hip disarticulation involves amputation through the hip joint capsule. This strong fibrous layer covers the anterior hip to the intertrochanteric line but leaves most of the femoral neck exposed posteriorly.
- Tumors can often extend to the ischiorectal fossa; this should be determined preoperatively by examining computed tomography (CT) and magnetic resonance imaging (MRI) scans. The ischiorectal fossa is an area bounded medially by the sphincter ani externus and anal fascia, laterally by the tuberosity of the ischium and obturator fascia, anteriorly by the fascia covering the transversus perinei superficialis, and posteriorly by the gluteus maximus and sacrotuberous ligament. Assessment for tumor extension to this area is particularly important in planning the flaps that will be used.

INDICATIONS

- Proximal tumors not extending above the midthigh
- Femoral diaphyseal tumors with proximal intramedullary extension
- Soft tissue sarcomas of the thigh with extension to the femur or neurovascular structures
- Unresectable local recurrences, particularly after radiation therapy has been used
- Pathological fractures that are not responsive to induction chemotherapy and immobilization
- Palliation of extensive tumors

IMAGING AND OTHER STAGING STUDIES

Computed Tomography and Magnetic Resonance Imaging

- CT is useful in showing the effect of the tumor on the structural integrity of the bone. It may also show extension into the soft tissues, especially in the ischiorectal fossa, hip joint, and groin. MRI shows the intraosseous spread of the tumor within the marrow and therefore is helpful in determining the level of amputation and the appropriateness of the hip disarticulation.

Bone Scan

- A bone scan is helpful in evaluating the bony involvement of the femur, pelvis, and acetabulum. Acetabular involvement is a contraindication to doing a hip disarticulation.

Angiography and Other Studies

- Angiography can help identify the external iliac, common femoral, and profundus arteries when preparing for surgery.

Biopsy

- A biopsy is warranted before most amputations. However, given the potential functional limitations and prosthetic needs of a hip disarticulation, a biopsy is definitely recommended before performing a hip disarticulation.

SURGICAL MANAGEMENT

- Lymph node involvement should be assessed before proceeding with a hip disarticulation. Lymph node involvement is a relative contraindication to performing a hip disarticulation unless the procedure is done for palliation.
- Hip disarticulations are often required after poor chemother-apy response or tumor aggressiveness. These situations increase the likelihood for close surgical margins, which can lead to local recurrences.
- All radiographic studies must be reviewed to ensure that there is no suggestion of tumor proximal to the lesser tuberosity. This would increase the risk of having positive or close margins.
- The development of the flaps is critical for optimal wound closure and healing. It is not uncommon to make flaps of unusual shape in performing a hip disarticulation for tumor of the middle or distal femur or thigh. Previous scars, radiated
fields, and the presence of a tumor mass all determine the best skin to be used. If possible, fasciocutaneous flaps should be constructed to promote wound healing.

Optimizing the patient’s overall health and nutritional status preoperatively is essential in promoting wound healing and decreasing perioperative complications.

Preoperative Planning

- Manipulation of more proximal venous structures can increase the likelihood of the development of deep venous thrombi. Often these more proximal thrombi can embolize and lead to fatal pulmonary emboli. In patients with a prior history of deep venous thrombosis or pulmonary emboli, the surgeon should consider placing a venous filter before surgery to minimize the risk of pulmonary emboli.

- An amputation is a life-altering event; both physical and emotional issues need to be addressed. Many patients find psychological counseling helpful, so the surgeon should ensure that these services are available in the perioperative period.

- Having patients meet with a prosthetist and a functional amputee can help manage expectations and provide answers about daily activities and function.

Positioning

- Since a hip disarticulation involves both anterior and posterior dissections, a semilateral or lateral position is often best.

Approach

- The major portions of the hip disarticulation are done through an anterior approach to the hip and groin. This facilitates exposure of the femoral triangle and muscle origins.

- Recently, Lackman et al3 published their technique using the lateral approach for hip disarticulations. This has the advantage of familiarity and provides access to both anterior and posterior structures.

### INCISION AND INITIAL EXPOSURE

- Bony landmarks to be identified include the pubic tubercle, anterior superior iliac spine, anterior inferior iliac spine, ischial tuberosity, and greater trochanter (TECH FIG 1A).

- The anterior incision starts 1 cm medial to the anterior superior iliac spine and continues distally to the pubic tubercle and over to the pubic bone to 2 cm distal to the ischial tuberosity and gluteal crease.

- If the buttock flap is extremely thick, the anterior portion of the incision should be moved laterally.

- The posterior incision starts about 2 cm anterior to the greater trochanter and extends to the back of the leg distal to the gluteal crease.

- The distance the incision is beyond the gluteal crease is directly proportional to the anteroposterior diameter of the patient’s pelvis.
DIVISION OF ANTERIOR HIP AND GROIN MUSCLES AND ISCHIAL TUBEROSITY RELEASE

- The sartorius muscle is located as it arises from the anterior superior iliac spine. It is dissected free from the surrounding fascia and then transected from its origin on the spine by electrocautery. The femoral sheath and fibroareolar tissue posterior to the femoral vessels are also incised by electrocautery. This dissection exposes the hip joint capsule (TECH FIG 2A).

- With the hip slightly flexed, a finger can be placed in a mediolateral direction under the iliopsoas to isolate the muscle, which can then be freed from its origin at the lesser trochanter (TECH FIG 2B). If an attempt is made to pass the finger beneath the muscle from lateral to medial, the very intimate attachments between the iliopsoas muscle and the rectus femoris muscle prevent this from being easily done. By sharp and blunt dissection the entire iliopsoas muscle is dissected until its insertion on the lesser trochanter is clearly defined. Several vessels of prominent size pass from the anterior surface of this muscle, and care should be taken to secure these vessels before their division. The iliopsoas muscle is severed at the level of its insertion onto the lesser trochanter.

- Next, the adductor muscles are released from the pelvis in a lateral to medial process. To preserve the obturator externus muscle on the pelvis, the surgeon locates its prominent tendon arising from the lesser trochanter. Locating this tendon identifies the plane between the pectineus muscle and the obturator externus; a difference in the direction of the muscle fibers of these two muscles is also apparent. A finger is passed beneath the pectineus muscle, and it is released at the level of its origin from the pubis by electrocautery (TECH FIG 2C). Beneath the pectineus muscle numerous branches of the obturator artery, vein, and nerve can now be visualized. The gracilis, adductor longus, adductor brevis, and adductor magnus are transected at their origins on the symphysis pubis. The obturator vessels and nerves usually bifurcate around the adductor brevis muscle. Branches of the obturator artery must be identified and secured during the dissection to prevent accidental rupture and retraction of the proximal ends up into the pelvis (TECH FIG 2D).

- The extremity is hyperabducted to localize the ischial tuberosity and the retracted cut ends of the adductor muscles. The circumflex femoral vessels should be visible and should be avoided. The semimembranosus, semitendinosus, and long head of the biceps are transected from their origin on the ischial tuberosity while preserving the quadratus femoris and sciatic nerve (TECH FIG 2E).

- Skin, subcutaneous fat, and fascia of Scarpa are incised to expose the aponeurosis of the external oblique.
- Saphenous vein branches are clamped, divided, and ligated.
- A moderate-sized artery, the superficial epigastric, and multiple branches of the external pudendal vessels are secured.
- The spermatic cord in men or the round ligament in women is identified, and care is taken to avoid injuring these structures.
- An incision made just below the inguinal ligament into the fossa ovalis exposes the femoral vein, artery, and nerve (TECH FIG 1B).

Individual silk ties are placed around the femoral vessels; first the artery and then the vein are tied in continuity. Right-angle clamps are placed between the ties, and the vessels are severed. The proximal ends of the vessels are further secured by a silk suture ligature placed proximal to the right-angle clamps. The femoral nerve is placed on gentle traction and ligated where it exits from beneath the inguinal ligament. When the femoral nerve is severed, it retracts beneath the external oblique aponeurosis, so that if a neuroma forms it will not be in a weight-bearing portion of the stump (TECH FIG 1C).

**TECH FIG 2** • A. Division of sartorius muscle and femoral sheath. B. Division of iliopsoas muscle at its insertion. The hip is flexed slightly to relax the iliopsoas muscle. *(continued)*
HIP JOINT CAPSULE INCISION AND DIVISION OF POSTERIOR MUSCLES

- All the anterior and posterior muscle groups have been divided. The joint capsule overlying the head of the femur is incised, and the ligamentum teres is transected by electrocautery (TECH FIG 3A).
- The patient’s torso is tilted from posterolateral to anterolateral. The incision is completed posteriorly through gluteal fascia (TECH FIG 3B). The tensor fascia lata and gluteus maximus muscles are divided in the depths of the skin incision. These are the only muscles not divided at either their origin or insertion in the procedure. Directly beneath these muscles is the rectus femoris muscle, which is transected at its origin on the anterior inferior iliac spine by electrocautery (TECH FIG 3C). The common tendon comprising contributions from the gluteus medius, gluteus minimus, piriformis, superior gemellus, obturator internus, inferior gemellus, and quadratus femoris muscles, is exposed after the division of the gluteus maximus. All these muscles are divided close to their insertions on the greater trochanter (TECH FIG 3D).

TECH FIG 3 • A. Incision of the anterior portion of the hip joint capsule. B. Completion of the skin incision. (continued)
RELEASE OF SPECIMEN AND CLOSURE

- Transection of the hip joint capsule is completed by incising the posterior portion of the capsule. The sciatic nerve is dissected free of surrounding muscle, transected, and allowed to retract beneath the piriformis muscle (TECH FIG 4A).
- The obturator externus and gluteus medius are sutured together over the acetabulum and joint capsule to help provide soft tissue coverage of the bony prominence (TECH FIG 4B).
- The gluteal fascia is elevated and secured to the inguinal ligament and the pubic ramus. Multiple stitches are placed bisecting the fascial edge that gather the gluteal fascia as it is secured to the inguinal ligament. Sutures are individually placed and then tied. Before closure of this posterior myocutaneous flap, suction catheters are placed beneath the gluteal fascia.
- The skin is closed with interrupted sutures. Again, care is taken to make sure that there is equal distribution of the excess tissue of the posterior flap. Not infrequently, additional suction catheters must be used to obliterate space within the subcutaneous tissue when the buttock flap is thick (TECH FIG 4C). Patency of the suction catheters must be maintained until drainage is diminished. Ambulation may proceed if the patient’s hemodynamic status permits on the first postoperative day.

TECH FIG 4 • A. Release of specimen. B. Approximation of obturator externus and gluteus medius over the joint capsule. (continued)
POSTOPERATIVE CARE

- A compressive dressing should be maintained for 3 to 5 days to minimize swelling. After this time the wound should be inspected and redressed.
- Drains should remain until the total daily output is minimal.
- Prosthesis fitting can begin when the wound swelling has decreased and the wound is completely healed. Usually this takes at least 4 to 6 weeks after surgery.

OUTCOMES

- The 5-year survival of patients after hip disarticulation done as the primary treatment is 32%. When done for local recurrence, the 5-year survival is 25%.
- Hip disarticulation has been shown to be very effective as a means of palliation for extensive tumors without other treatment options. It thus improves the quality of life of these patients.
- Prosthetic use in this population is usually lower than that seen in groups with more distal amputations. Use ranges from 5% to 60% of amputees. Problems with artificial limb use and reasons for the lack of limb use have included limb weight and inconvenience with toileting. Despite this, all patients should be offered an artificial limb.

- Many patients with hip disarticulations are very functional, and one study found that most were even able to drive whether or not they used a prosthesis.

COMPLICATIONS

- The local recurrence rate is 2% to 12% and is usually higher in patients whose amputation was done for local recurrences or if there were close margins.
- Wound healing problems can arise from seroma or hematoma development. The use of drains can help decrease the risk of seromas and hematomas.

REFERENCES

BACKGROUND

- The proximal femur and the midfemur are common sites for primary bone sarcomas and metastatic tumors.
- Formerly, patients who were candidates for extensive femoral resection because of malignant tumor were considered a high-risk group for limb-sparing procedures because of the extent of bone and soft tissue resections and the anticipated poor function postoperatively, as well as the deleterious consequences of adjuvant chemotherapy and radiation therapy. Hip disarticulation or hemipelvectomy were, therefore, the classic treatment options for patients with large lesions of the proximal femur or midfemur. Both procedures were associated with a dismal functional, aesthetic, and psychological outcome.
- Today, improved survival of patients with musculoskeletal malignancies, developments in bioengineering, and refinements in surgical technique have enabled these patients to undergo limb-sparing procedures. Local tumor control is good, as is the probability of a functional extremity. Proximal and total femur resection became a reliable surgical option in the treatment of primary bone sarcomas and metastatic bone disease and, more recently, of a variety of nononcologic indications. These latter indications include failure of internal fixation, severe acute fractures with poor bone quality, failed total hip arthroplasty, chronic osteomyelitis, metabolic bone disease, and various congenital skeletal defects.
- Methods of skeletal reconstruction include resection arthrodesis, massive osteoarticular allograft, endoprosthetic reconstruction, and prosthetic allograft composites.
- Osteoarticular allografts, which were popular in the 1970s and 1980s, aim to restore the natural anatomy of a joint by matching the donor bone to the recipient’s anatomy, but they are associated with increased rates of infection, nonunion, instability, fracture, and subchondral collapse and thus ultimate failure.
- Introduced in the mid-1980s, modular prostheses revolutionized endoprosthetic reconstruction. The modular system enables the surgeon to measure the actual bone defect at the time of surgery and select the most appropriate components to use in reconstruction. Components of these interchangeable systems include articulating segments, bodies, and stems of varying lengths and diameters. Design features include extensive porous coating on the extracortical portion of the prostheses for bone and soft tissue fixation and metallic loops to assist in muscle reattachment.

ANATOMY

- The intracapsular location of the femoral neck makes it biologically possible for tumors of the proximal femur to spread into the hip and adjacent synovium, joint capsule, and ligamentum teres. The ligamentum teres provides a mechanism for transarticular skip metastases to the acetabulum. Fortunately, intra-articular involvement is rare and usually occurs after a pathologic fracture. The capsule can be preserved and an intra-articular resection of the femur is usually possible. In the case of capsular or acetabular involvement or both, extra-articular resection of the hip should be considered.
- The greater trochanter, which is removed with the surgical specimen, serves as the attachment site for the hip abductors. The tendon stump should be marked and preserved for reattachment to the prosthesis.
- The lesser trochanter, which is removed with the surgical specimen, serves as the attachment site for the psoas muscle. The tendon stump should be marked and preserved for reattachment to the prosthesis. The combined attachment of the abductors and psoas to the lateral and medial aspects of the prosthesis, respectively, preserves balanced prosthetic range of motion.
- The femoral artery descends the thigh almost vertically within the sartorial canal toward the adductor tubercle of the femur, enters the opening of the canal of Hunter at the adductor magnus muscle, and becomes the popliteal artery. The profunda femoris artery branches to the medial aspect of the femoral artery 4 cm below the inguinal ligament. Occasionally, the profunda femoris is ligated and resected en bloc with large tumors of the proximal femur.

INDICATIONS

- Primary bone sarcomas
- Benign aggressive tumors associated with extensive bone destruction
Metastatic tumors associated with extensive bone destruction (FIG 4B)

Nononcologic indications include failure of internal fixation, severe acute fractures with poor bone quality, failed total hip arthroplasty with segmental bone loss below the level of the lesser trochanter, chronic osteomyelitis, metabolic bone disease, and various congenital skeletal defects (FIG 4C).

Proximal femur resection is performed for metaphyseal-diaphyseal lesions that (1) extend below the lesser trochanter, (2) cause extensive cortical destruction, and (3) spare at least 3 cm of the distal femoral diaphysis. Total femur resection is performed for diaphyseal lesions that (1) extend proximally to the lesser trochanter and distally to the distal diaphyseal-metaphyseal junction and (2) cause extensive bone destruction (FIG 4D).

IMAGING AND OTHER STAGING STUDIES

Proximal and total femur resections are major surgical procedures that necessitate an especially detailed preoperative evaluation. Physical examination and imaging studies are done to determine (1) the extent of bone resection and dimensions of the required prosthesis, (2) the extent of soft tissue...
resection and reconstruction possibilities, and (3) the proximity of the tumor to the femoral vessels, femoral nerve, and sciatic nerve.

- Most complications can be avoided by predicting their likelihood before surgery and modifying the surgical technique accordingly. A full range of imaging studies is needed, including plain radiography, computed tomography (CT), and magnetic resonance imaging (MRI) of the whole femur and the hip and knee joints. CT and plain radiography are used to evaluate the extent and level of bone destruction; MRI is used to evaluate the medullary and extraosseous components of the tumor, the intracapsular tumor extension, and the presence of skip metastases within the femoral canal and in the acetabulum.

- Angiography of the iliofemoral vessels is essential before resection of tumors of the proximal femur. Vascular displacement is common when tumors have a large, medial extraosseous component: the profundus femoral artery is particularly vulnerable to distortion or, less commonly, to direct incorporation into the tumor mass. If the tumor has a large medial extraosseous component and ligation of the profundus femoral artery is anticipated, the presence of a patent superficial femoral artery must be documented by angiography before surgery. Preoperative embolization may be useful to prepare for resection of metastatic vascular carcinomas if an intralesional procedure is anticipated. Metastatic hypernephroma is an extreme example of a vascular lesion that may bleed extensively and cause exsanguination if an intralesional procedure is done without prior embolization.

**SURGICAL MANAGEMENT**

- Limb-sparing surgery that involves endoprosthetic replacement of the proximal or the entire femur is done in three steps: tumor resection, endoprosthetic reconstruction, and soft tissue reconstruction. The technique of proximal femur endoprosthetic replacement is described in the following paragraphs. The additional steps required for total femur resection are described at the end of the appropriate sections.

- In general, surgery for metastatic tumors to the proximal femur is not different from surgery for primary sarcomas of bone. The main differences are that metastatic lesions have a smaller extraosseous component than primary lesions, and the surrounding muscles are usually invaded by the metastatic lesions (as opposed to the “pushing” border of bone sarcomas).
TUMOR RESECTION

Position and Incision
- The patient is placed in a lateral position and a long lateral incision is made extending from 3 to 4 cm proximal to the greater trochanter to the distal two thirds of the thigh (TECH FIG 1A,B). An ilioinguinal extension to that incision is added if the tumor has an extensive, medial soft tissue component along the proximal femur. This approach allows exposure of the proximal third of the femur and the retrogluteal area and allows for identification of the femoral canal, femoral triangle, superficial and profundus femoral artery, and sartorial canal.

- Posterior reflection of the gluteus maximus muscle exposes the retrogluteal area and allows for identification of the femoral canal, femoral triangle, superficial and profundus femoral artery, and sartorial canal.

- The sciatic nerve lies directly posterior to the external rotators. In general, as primary bone sarcomas expand, the external rotators are pushed outward and act as a protective barrier to the sciatic nerve. As such, the sciatic nerve is often not in its usual anatomic location in these patients and must be identified early, isolated, and mobilized posteriorly to prevent injury. The abductors are identified with their anterior and posterior intervals. If there is no tumor involvement, the greater trochanter or small bony attachment is osteotomized; otherwise, the abductors are transected through their tendinous attachments and retracted, exposing the hip joint and acetabulum (TECH FIG 2A,B).

- The sciatic nerve lies directly posterior to the external rotators. In general, as primary bone sarcomas expand, the external rotators are pushed outward and act as a protective barrier to the sciatic nerve. As such, the sciatic nerve is often not in its usual anatomic location in these patients and must be identified early, isolated, and mobilized posteriorly to prevent injury. The abductors are identified with their anterior and posterior intervals. If there is no tumor involvement, the greater trochanter or small bony attachment is osteotomized; otherwise, the abductors are transected through their tendinous attachments and retracted, exposing the hip joint and acetabulum (TECH FIG 2A,B).

Vastus Lateralis Reflection
- The vastus lateralis is transected from its origin at the vastus ridge and reflected distally, and the posterior perforating vessels are ligated (TECH FIG 3A,B). The vastus lateralis must be preserved because of its future role in soft tissue coverage of the prosthesis: it will be advanced proximally and sutured to the abductors (see...
TECH FIG 1 • Illustration (A) and operative photograph (B) showing a long lateral incision used for resection of the proximal or the whole femur. C,D. The incision is brought distally to the anterolateral aspect of the patellar tendon and tibial tuberosity for exposure of the entire femur. If the tumor has medial or posterior soft tissue extensions at the distal femur that require dissection at the medial aspects of the knee and popliteal fossa, the incision is curved medially at its distal part. (A: Reprinted with permission from Clin Orthop Relat Res 2000;375:218–230.)

TECH FIG 2 • The proximal femur after posterior retraction of the gluteus maximus and exposure of the retrogluteal area, external rotators, sciatic nerve, abductors, and posterior capsule. Because of tumor extension into the greater trochanter in the illustrated case, the abductors are identified and transected through their tendinous attachments and retracted, exposing the hip joint and acetabulum. If the greater trochanter is not involved by tumor extension, it is osteotomized and reflected with the abductor tendon. (A: Reprinted with permission from Clin Orthop Relat Res 2000;375:218–230.)
“Soft Tissue Reconstruction” below). Care is taken not to ligate its main pedicle, which crosses anteriorly and obliquely along the rectus femoris fascia.

- The femoral nerve is identified below the fascia (TECH FIG 3A,B). The superficial and profundus femoral artery and vein are identified in the sartorial canal and retracted. If they are invaded by the soft tissue extension of the tumor, the profundus artery and vein may be ligated just distal to their takeoff from the common femoral vessel.

Detachment of Posterior Hip Musculature and Capsule, Dislocation of Femur

- With the retrogluteal area exposed, the rotator muscles are detached en bloc 1 cm from their insertion on the proximal femur. The hip joint capsule has a major role in securing and stabilizing the head of the prosthesis within the acetabulum, and if not invaded by tumor, it should remain intact.

- The capsule is opened longitudinally along its anterolateral aspect and detached circumferentially from the femoral neck. The femur is dislocated anterolaterally. Special care is taken not to fracture the femoral neck, especially if a primary bone sarcoma is being resected. The acetabulum is inspected for evidence of joint involvement (TECH FIG 4A,B). If total femur resection is performed, a tibial osteotomy is carried out in the same manner as a standard knee joint arthroplasty, in which about 1 cm of bone is removed, the cut is perpendicular to the long axis of the tibia, and the insertion of the biceps femoris muscle is retained.

- If delicate dissection around the popliteal vessels is anticipated, an anteromedial arthrotomy should be done and the popliteal fossa should be approached from its medial aspect. The total femur is resected en bloc with the vastus intermedius muscle, but the vastus lateralis, rectus femoris, patella, and patellar tendon are preserved. Because malignant tumors of the distal femur rarely penetrate beyond the vastus intermedius muscle or patellar surface, the patella can be preserved in the large majority of the cases.

Distal Femoral Osteotomy and Release of Medial Structures

- Femoral osteotomy is performed at the appropriate location, as determined by the preoperative imaging studies. In general, 3 to 4 cm beyond the farthest point is appropriate for primary sarcomas and 1 to 2 cm for metastatic carcinomas. An oscillating saw is used for the osteotomy, and a malleable retractor is placed medially to the femoral shaft to prevent inadvertent injury to the soft tissues. The cut should be at a right angle to the shaft (TECH FIG 5).

- It is important not to distract the extremity after removal of the proximal femur to avoid placing tension on the sciatic nerve and femoral vessels. If total femur resection is performed, a bicipital osteotomy is carried out in the same manner as a standard knee joint arthroplasty, in which about 1 cm of bone is removed, the cut is perpendicular to the long axis of the tibia, and the insertion of the biceps femoris muscle is retained.

- After femoral osteotomy or disconnection of the entire femur after bicipital osteotomy, the femur is retracted laterally. The remaining medial structures are now clearly visible: they consist of the psoas and adductor muscles, which should be identified either now or at some point before the femur is osteotomized. The muscles are serially dissected, clamped with Kelly clamps, and tagged with Dacron tapes. Care is taken to dissect the profundus femoral artery.

- If oncologically indicated, the profundus femoral artery may be ligated, but only after patency of the superficial femoral artery has been confirmed.
Chapter 24  PROXIMAL AND TOTAL FEMUR RESECTION WITH ENDOPROSTHETIC RECONSTRUCTION

TECH FIG 4 • Illustration (A) and operative photograph (B) showing detachment of the posterior hip musculature and capsule. Illustration (C) and operative photograph (D) showing the arthrotomy of the knee joint that is required to accomplish total femur resection. An anterolateral arthrotomy using the initial lateral incision is usually feasible. However, if the tumor extends toward the popliteal fossa and delicate dissection of the popliteal vessels is anticipated, anteromedial knee exposure and medial exposure of the popliteal fossa are done as for resection of the distal femur. The femur will be removed with the overlying vastus intermedius; the rectus femoris and patella are spared. (A: Reprinted with permission from Clin Orthop Relat Res 2000;375:218–230; C: Courtesy of Martin M. Malawer.)

TECH FIG 5 • Distal femur osteotomy and removal of the proximal femur. The femoral osteotomy is done 3 to 4 cm beyond the farthest point of tumor extension for primary sarcomas and 1 to 2 cm for metastatic carcinomas. (A: Courtesy of Martin M. Malawer.) (continued)
ENDOPROSTHETIC RECONSTRUCTION

- After resection of the proximal femur, the length of the resected specimen, the size of the femoral head, and the diameter of the distal medullary canal are measured. A trial femoral head prosthesis is used to test the suction fit. The proximal end of the remaining femur should be kept well padded to avoid injuring the superficial femoral artery. A frozen section from the canal is evaluated for evidence of residual tumor before reaming the femoral canal.

Reaming the Intramedullary Canal

- The largest possible stem diameter should be chosen, especially for primary tumors. A 1-mm cement mantle is required around the stem. The intramedullary canal is therefore reamed 2 mm larger than the chosen stem diameter (TECH FIG 6).

Trial Articulation

- Modular trial prosthetic components should be assembled to match the length of the resected specimen. These include body parts, a neck, and prosthetic head (TECH FIG 7A–C). Total femur prostheses are joined to the tibial component with a rotating hinge mechanism (TECH FIG 7D,E). After trial positioning of the prosthesis, the pulses are palpated distally: a shorter prosthesis will be required if they are diminished. The joint capsule is pulled over the femoral head component, and the range of motion of the hip joint is tested. The prosthesis should be stable in flexion, adduction, and internal rotation.
TECH FIG 7 • (continued) C. Trial articulation. Leg length must be measured and the neurovascular bundle evaluated for excessive tension. Schematic (D) and plain radiograph (E) of a total femur prosthesis, which is joined to a tibial component via a rotating hinge mechanism. (C–E: Courtesy of Martin M. Malawer.)

**Prosthetic Assembly and Implantation**

- The modular prosthesis is assembled and cemented into the medullary canal. The orientation of the prosthesis is critical. With the linea aspera as the only remaining anatomic guideline, the prosthesis is placed with the femoral neck anteverted about 5 to 10 degrees with respect to an imaginary perpendicular line from the prosthesis and a line is drawn from the linea aspera through the body of the prosthesis (TECH FIG 8).

- Two bags of bone cement are usually required, and the cementing technique consists of pulsatile lavage, use of an intramedullary cement restrictor, reduction of the cement by centrifugation, use of a cement gun, pressurization of the cement, and enhancement of the prosthesis–cement interface by precoating the proximal portion of the femoral or tibial stem with bone cement. While the bone cement hardens, the surgeons continuously verify the correct positioning of the prosthesis.

**TECH FIG 8** • The prosthesis is positioned in 5 to 10 degrees of anteversion, with the linea aspera being the only remaining anatomic guideline for proximal femur endoprosthetic replacements and the tibial tuberosity for total femur endoprosthetic replacements. (Courtesy of Martin M. Malawer.)

**SOFT TISSUE RECONSTRUCTION**

- Special attention is given to re-establishing hip stability and providing adequate muscle coverage of the prosthesis. The remaining hip capsule is sutured tightly with a 3-mm Dacron tape (Deknatel, Falls River, MA) around the neck of the prosthesis, forming a noose that provides immediate stability (TECH FIG 9A–D). Dacron is a nonabsorbable synthetic polyester (polyethylene-terephthalate) that allows approximation of the cut ends of the joint capsule under considerable tension. It provides the initial mechanical support needed for healing and scar formation throughout the capsule. The surgeon cannot dislocate the prosthesis in a capsule that is
adequately closed. Stabilization of the prosthesis is reinforced by rotating the external rotator muscles proximally and suturing them to the posterolateral aspect of the capsule. The psoas muscle is rotated anteriorly and tenodesed to the anterior capsule as additional reinforcement (TECH FIG 9E,F).

The extracortical component of the prosthesis can be used for additional bone and soft tissue fixation in the form of a noose around the prosthesis. Bone struts, either autografts or allografts, are held circumferentially with Dacron tape to the prosthesis–host bone interface. Theoretically, this procedure will prevent debris from entering the bone–cement interface, thereby reduce the possibility of aseptic loosening.

If the greater trochanter had been resected en bloc with the surgical specimen, the remaining abductor tendon is attached with Dacron tape to the lateral aspect of the prosthesis through a metal loop. If there is a remaining fragment of the greater trochanter, it is fixed to the prosthesis with a cable grip system (TECH FIG 9G). Dynamic reconstruction is obtained by tenodesing the vastus lateralis to overlie the abductor muscle fixation. The remaining muscles are sutured to the vastus lateralis anteriorly and the hamstrings posteriorly (TECH FIG 9H,I).

The wound is closed over a 28-gauge chest tube that is attached to a continuous suction at 20 cmH2O (TECH FIG 9J). The patient is placed in balanced suspension or tibial pin traction with the hip elevated and flexed 20 degrees.

TECH FIG 9 • A–D. The remaining hip capsule is sutured tightly with a 3-mm Dacron tape (Deknatel, Falls River, MA) around the neck of the prosthesis. E. The psoas muscle is rotated anteriorly and tenodesed to the anterior capsule as additional reinforcement. F. Alternatively, a circumferential polyethylene-terephthalate tube may be applied on the prosthesis to which the surrounding muscles and tendons can be sutured. G. Fixation of the greater trochanter to the lateral aspect of the prosthesis with a cable grip system. (continued)
**POSTOPERATIVE CARE**

- The extremity is kept in balanced suspension for at least 5 days. An abduction brace is customized for the patient. Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.
- Postoperative mobilization with an abduction brace and weight bearing as tolerated are continued for 6 weeks. Active hip abduction is required before the brace can be removed and before unprotected, full weight bearing can be allowed.

**OUTCOMES**

- More than 80% of patients who undergo proximal or total femur resection report good to excellent function.\(^1\) Most of them do not require a walking aid (crutches, walker, or cane), although some abductor insufficiency and Trendelenburg gait are common.
- No differences in function were found between patients who underwent proximal femur replacement and those who underwent total femur replacement.\(^1\)
- Dislocations of the prosthesis have become rare due to the combined use of capsular repair and reconstruction of the abductor mechanism. Because of the excellent blood supply around the proximal thigh and hip joint and the options for prosthetic coverage with viable muscle tissue, flap ischemia, deep infections, and prosthetic loosening are rare.

**COMPLICATIONS**

- Deep infection
- Dislocation
- Abductor insufficiency and Trendelenburg gait
- Local tumor recurrence
- Prosthetic loosening

**REFERENCES**

2. Enneking WF, Shirley PD. Resection-arthrodesis for malignant and potentially malignant lesions about the knee using an in-
BACKGROUND

- Ralph C. Marcove (Memorial Sloan Kettering Cancer Center) and Kenneth C. Francis (New York University Medical Center) introduced limb-sparing resection in the early 1970s for the management of malignant bone tumors, initially for osteosarcoma of the distal femur. The introduction of effective chemotherapy agents (doxorubicin [Adriamycin] and methotrexate) at the same time was a major impetus to the development of these procedures. These surgeons hoped by combining surgery with chemotherapy, either preoperatively or postoperatively (termed adjuvant chemotherapy), limb-sparing surgery would be safe for the patient and would permit a limb-sparing resection.

- Distal femoral endoprosthetic reconstruction has undergone an evolution of surgical techniques and manufacturing changes (initially by Howmedica, Inc., Rutherford, NJ), making it one of the most satisfying orthopaedic oncology procedures available today. Forging of components has greatly diminished mechanical failure problems, and modularity has increased the indications for its use. Muscle-sparing and soft tissue coverage techniques have minimized wound healing problems.

- The three major steps in limb-sparing surgery—wide excision with good oncologic margins, reliable reconstruction of the skeletal defect, and adequate muscle transfer and soft tissue coverage—have formed the basis for reliable and safe limb-sparing resections and reconstruction for both low- and high-grade bone sarcomas. Most clinical experience has been gained in treating osteosarcoma of the bone. The most common site is the distal femur and the proximal tibia. These techniques have subsequently been used for other bony sarcomas and recurrent benign tumors and more recently in the treatment of failed allograft and complicated, multifailed total knee arthroplasties.

- The goal is to have an adequate oncologic resection while maintaining enough muscle to permit a painless functional result. The techniques outlined in this chapter are based on the senior authors’ (MM, JJE) 51 years of combined surgical experience, with approximately 440 distal femoral reconstructions since 1979.

ANATOMY

- The surgeon must be extremely knowledgeable of not only the bony anatomy and the specific endoprosthesis to be used but also the vascular anatomy, soft tissue structures, and potential local muscle flaps and the many techniques involved in a limb-sparing resection (FIG 1).

Sartorial Canal

- The sartorial canal occupies the space between the vastus medialis, sartorius, and adductor magnus muscles in which the superficial femoral artery passes the medial aspect of the thigh (adductor hiatus) and then enters the popliteal space. In patients whose tumors are longer than 13 cm, the sartorial canal is often displaced. The vessels within the canal are usually protected by the deep fascia of the vastus medialis and a tough fascia surrounding the vessels. This fascia border is rarely penetrated by tumor.

Knee Joint

- The knee joint is rarely directly involved by sarcoma. The main mechanisms of knee joint contamination are inappropriate biopsy, extension of tumor along the intra-articular cruciate ligaments, and pathologic fracture. The knee joint can reliably be evaluated by computed tomography (CT) and magnetic resonance imaging (MRI). If the physical examination reveals any evidence of effusion, the knee joint should be aspirated and histologic samples obtained. A hemarthrosis usually indicates tumor involvement of the synovium. This is a rare event but not an indication for amputation.

Popliteal Space

- The popliteal space contains the popliteal artery and vein and the sciatic nerve. The popliteal vessels enter the popliteal space from the medial aspect through the adductor hiatus as the vessels exit the sartorial canal. The popliteal vessels are evaluated by CT with contrast, MRI, and plain angiography.

- It is rare to have direct vessel involvement by tumor. The vessels may be displaced as the tumor grows posteriorly, but usually there is a normal border or margin of popliteal fat.

- Exploration of the popliteal space is the first step in determining the feasibility of a limb-sparing procedure. The popliteal vessels are dissected out and the geniculate vessels are ligated. If the vessels are free of tumor, resection can usually be performed safely.

![FIG 1 • Cross-sectional anatomy of the distal femur.](image-url)
FIG 2 • A. Evolution of the distal femoral endoprosthesis. Composite No. 1: The Waldius knee mechanism, introduced in 1951, had a fixed metal on hinge. No. 2 The Spherocentric distal femoral endoprosthesis was developed by Harry Matthews, MD, in 1975 and first implanted in 1977. A metal ball and polyethylene cupola connected the tibial and femoral components. No. 3: The original kinematic rotating-hinge knee was introduced in 1980. The vitalium hollow body was casted by the lost-wax method, and a custom Zickle nail stem was welded to it. No. 4: Circumferential porous ingrowth beads were introduced in 1985 to allow for bone incorporation. In reality little bone ingrowth occurred, but protective soft tissue ingrowth did. No. 5 Modularity was introduced in 1988. The condyles and femoral stems were forged and were coupled to titanium segments by Morse taper locks. Since its introduction in 1980 by Peter Walker for Howmedica, the kinematic rotating-hinge knee mechanism has remained virtually unchanged except for a slight increase in the diameter of the axle and the polyethylene bushings. The rotating-hinge knee concept has now been universally adopted as the preferred knee mechanism for distal femoral endoprosthetic reconstructions.

B. A Guepar prosthesis (simple hinge) was used in the early 1970s before the development the rotating-hinge prosthesis. C. Custom prosthesis used during the 1980s. The knee joint is a rotating hinge consisting of bushings, axles, and a rotating poly component that is inserted into the tibia. D. The modular replacement system was first used (National Cancer Institute) in 1988 and was approved by the U.S. Food and Drug Administration in 1991. This system consists of a joint component, multiple body segments, and stems of various diameters. This system can replace the proximal femur, distal femur, total femur, or proximal humerus. The original system was developed by the senior author (MM) in conjunction with the engineers (lead engineer George Corsi) at Howmedica (Rutherford, NJ). This system, now known as the Global MRS system, is manufactured by Stryker Orthopedics (Mahwah, NJ).
A frozen section of the popliteal fat or adventitia of the popliteal vessels should be obtained intraoperatively. If there is obvious vascular involvement, the vessels can be replaced by vascular graft.

The popliteal vein is usually not repaired because it rarely stays patent after surgery.

### Anterior and Posterior Cruciate Ligaments

- The cruciate ligaments are occasionally involved by direct tumor extension from the distal femur. This occurs through the bone–tendinous junction of the intercondylar notch of the distal femur. There is no cartilage in this area to act as a barrier to tumor growth.
- MRI is occasionally helpful in determining cruciate ligament involvement.
- Tumor nodules of the anterior and posterior cruciates occasionally present with a hemorrhthrosis. The most common finding at resection is tumor nodule involvement of the cruciates. This does not rule out a limb-sparing procedure. The cruciate ligaments as they attach to the proximal tibial plateau can be resected en bloc with the proximal tibial cut. This is a safe procedure that avoids the need for a true extra-articular resection.

### INDICATIONS

- Endoprostheses were initially used solely for reconstruction after resection of malignant bone tumors. Manufacturing time could be as long as 3 months, an interval that permitted induction chemotherapy. Endoprosthetic reconstructions proved to be enduring, and the designs have evolved ([FIG 2](#)). Modularity, which made for immediate availability, permitted the expansion of the indications for distal femoral endoprosthetic reconstruction to some stage 3 giant cell tumors of bone; metastatic disease where conventional intraleisional procedures cannot reasonably be done, possibly 10% of metastatic cases; complex supracondylar fractures in elderly osteoporotic patients; failed internal fixation of distal femoral fractures; failed allograft or total knee reconstructions; and as a primary knee replacement system in patients with a severe flexion contracture where bone and ligament resection would lead to instability with conventional knee replacement systems.

### PATIENT HISTORY AND PHYSICAL FINDINGS

- The average age of patients with high-grade osteosarcomas is 5 to 30 years; the median is 16 to 21 years. Surface osteosarcomas occur in the third decade and are more common in women.
- Patients with high-grade osteosarcoma almost always initially complain of pain during the day that is not associated with activity. All patients complain of a dull aching pain and only later of night pain.
- Thirty to 40% of patients have a history of local trauma. There is no causal relationship of trauma to the tumor except that it brings the patient to medical attention and the physician orders a radiograph, which always shows the tumor. This has been termed “traumatic determinism.”

Classic high-grade osteosarcoma presents with pain. Parosteal osteosarcoma (surface osteosarcoma) usually presents with a mass and not pain ([FIG 3](#)).

Parosteal osteosarcomas are most common in the posterior aspect of the distal femur. They represent less than 4% of all osteosarcomas. Popliteal fullness is a common finding. Plain radiographs can often distinguish a classic from a parosteal osteosarcoma.

- There may be tenderness on examination. The regional lymph nodes are normal. Osteosarcomas spread hematogenously. Infection is rarely a consideration.
- Pathological fracture occurs in less than 1% of osteosarcomas. Fractures usually occur through the purely osteolytic variant (about 25% of all osteosarcomas), which has minimal mineralized tumor matrix.
- A soft tissue, extraosseous mass occurs in more than 90% of high-grade osteosarcomas.
- An effusion usually indicates tumor involvement of the joint or pathological fracture.
- Distal pulses are usually normal and symmetrical. Decreased pulses may represent tumor involvement.
- Leg edema may represent popliteal vein occlusion or thrombus.
- Enlarged groin lymph nodes may represent lymph node metastasis, but this is rare. Biopsy should be considered.
- Popliteal lymph node enlargement is extremely rare (except for Ewing sarcoma or lymphoma).

### IMAGING AND OTHER STAGING STUDIES

- Diagnostic imaging should include plain radiographs, a technetium-99 bone scan, an MRI of the entire femur, and a CT scan of the distal femur ([FIG 4](#)), as well as angiography. Three-dimensional CT angiograms have recently replaced routine angiography. Preoperative staging studies focus on the four anatomic structures discussed above. This permits the surgical team to determine the type of surgery, placement of the incision, the need for intra- or extra-articular resection, and the biopsy site and technique.
- Plain radiographs correlate very well with the extent of the tumor when a Codman triangle is present.
- A technetium-99 scan shows the extent of the tumor within the femur as well as the presence of skip metastases. Multicentric disease or metastases to other bones can be determined from this test as well. The early and pool phases of the bone scan demonstrate the vascularity of the tumor and tend to correlate with the chemotherapy effect (ie, tumor necrosis).
FIG 4 • A. Schematic illustration depicting the preoperative studies needed for sarcomas of the distal femur. MRIs, CT scans, bone scans, and angiography are required. B,C. AP and lateral radiographs of a patient with a secondary chondrosarcoma arising from an osteochondroma. D. Posterior projection of a technetium-99 bone scan in a patient with a sarcoma of the distal femur. No skip metastases are noted. The uptake on the scan correlates well with the extent of tumor within the bone. E. The CT scan of the patient in Fig. 4B,C clearly shows the medial osteochondroma stalk from which the secondary chondrosarcoma arose. A posterolateral osteochondroma is also noted. Although soft tissue extension of the tumor is apparent, it is less well delineated than on the MRI. F,G. Coronal and cross-sectional MRIs of the patient.
A femoral MRI best shows the extraosseous extent of the tumor as well as its proximal and distal extent within the medullary canal. This study is the most accurate in detecting skip metastases.

CT scans are complementary to MRI scans and can show the quality of the bone stock at the intended level of resection.

Angiography or three-dimensional CT angiography can be used to evaluate the superficial femoral and popliteal arteries. This is especially important if there is a large posterior or medial extraosseous component. The late arterial phase of the angiogram or venous phase will show residual tumor blush. The degree of remaining vascularity correlates well with the tumor necrosis (FIG 5A,B). An unresponsive tumor as shown by a tumor blush requires a wider margin than a good responder (no tumor blush). More recently, three-dimensional CT angiography has replaced traditional angiograms; it shows the vascular anatomy well (FIG 5C–F).

**FIG 5**  
A. Angiography after induction chemotherapy. A. Anteroposterior view. B. Lateral view showing the absence of a tumor blush. This is the most reliable finding of all preoperative staging studies that can predict tumor response. This patient had 100% chemonecrosis. C. Three-dimensional angiography is being evaluated in the treatment of bony tumors. C,D. Lateral and posterior views of the distal sarcoma. The popliteal artery is displaced. The extraosseous component is not visualized because there is no bony formation. E,F. Secondary chondrosarcoma of the proximal tibia. Lateral and posterior views showing excellent visualization of the popliteal artery and its trifurcation (arrows). A 64- or 246-slice CT scanner is required, similar to coronary angiography.
Together these studies help to determine the resectability of the tumor as well as the desired level of the femoral osteotomy. A comprehensive knowledge of prosthetic stem lengths and widths is necessary to be sure that adequate proximal bone stock is available to proceed with endoprosthetic reconstruction.

**SURGICAL MANAGEMENT**

- Surgical guidelines for limb-sparing surgery are as follows:
  - The major neurovascular bundle (popliteal vessels) must be free of tumor.
  - The resection of the affected bone should leave a wide margin and a normal muscle cuff (ie, 1 to 2 cm) in all directions (**Fig 6**).
  - All previous biopsy sites and all potentially contaminated tissues should be removed en bloc. All needle biopsy tracts must be removed (**Fig 7A**).
  - To avoid intraosseous tumor extension, bone should be resected 3 to 5 cm beyond abnormal uptake, as determined by preoperative studies.
  - The adjacent joint and joint capsule should be resected.
  - Adequate motor reconstruction must be accomplished by regional muscle transfers.
  - Adequate soft tissue coverage is needed to decrease the risk of skin flap necrosis and secondary infection. A medial gastrocnemius rotation flap provides excellent coverage of the prosthesis when required.
  - Careful attention to the patient’s general condition is critical in the timing of limb-sparing procedures in cancer patients. Patients undergoing preoperative chemotherapy (**Fig 7B,C**) and radiation therapy (Ewing sarcoma) need an adequate hiatus before surgery. In general, surgery can proceed 2 to 3 weeks after these treatments are completed. The white count and platelet count need to be within a safe range and rising, and the skin must have recovered from the effects of radiation and must be nonerythematous.
  - When the procedure is used for a salvage reconstruction after failed internal fixation, failed total joint arthroplasty, or allograft procedures, a past history of infection can bode poorly if it is not completely eradicated before surgery.

**Preoperative Planning**

- The intended level of resection should be determined before the patient comes to the operating room. A careful review of the diagnostic tests should confirm this location and should
confirm that there is adequate bone stock left to accept the femoral stem, in terms of both length and width. The distal femur should be resected with a safe oncologic margin (3 to 4 cm of normal marrow). The extremity lengths should be equal to within millimeters. To achieve this, intraoperative marks and measurements are made to ensure that the length before resection equals the reconstruction length.

When planning the primary resection and reconstruction, the surgeon should also be planning an amputation or revision. Ideally the level of amputation should be at the same level it would have been had amputation been chosen as the original procedure to achieve local control. The surgeon should plan how he or she will revise this reconstruction in the event of infection or mechanical failure. The real goal would be to retain the patient’s own hip and not go to a total femur replacement unless necessary, as this requires rehabilitating two joints in series, which is always a greater challenge for the patient.

Positioning

- In the preoperative area or as anesthesia is being induced, the patient is given intravenous antibiotics. One gram of vancomycin is slowly infused over 1 hour, and this is repeated every 12 hours until the drains are removed. A single 80-mg dose of gentamicin or tobramycin is also given. An epidural catheter is routinely used for postoperative pain management.
- After anesthesia is induced, a urinary catheter is placed. For the medial approach the patient is placed in the supine position with the entire leg, including the inguinal area, prepared. This provides adequate access to the proximal femoral vessels.
- A tourniquet is not used. A folded sheet placed transversely under the sacrum can elevate the pelvis to permit better access for draping. If the lateral approach is used, then the patient is placed in the lateral decubitus position on a beanbag with an axillary roll. A standard 10-minute preparation is performed, generally iodine-based.

Approach

- The preferred approach is a medial longitudinal approach with exploration of the superficial femoral and popliteal vessels. All vessels that feed the tumor and distal femur are tied off (FIG 8). A lateral approach is used only when access to the proximal femur is needed for cross-pin stem fixation or when little residual proximal femur remains.

RESECTION AND RECONSTRUCTION OF THE DISTAL FEMUR THROUGH A LONGITUDINAL MEDIAL APPROACH AND PREPARATION FOR CEMENTING THE TIBIA, PATELLA, AND FEMORAL COMPONENTS

Position and Dissection

- The patient is in supine position with the leg and inguinal area prepared out (TECH FIG 1A).
- The incision is longitudinal, following the sartorius muscle from proximally in the thigh distal to beyond the tibial tubercle (TECH FIG 1B).
- Any biopsy tract should be kept in continuity with the underlying tumor. Because the routine approach for primary tumors is medial, lateral or anterior open biopsy tracts need to be ellipsed and kept in continuity with the underlying tumor.
- The saphenous nerve is identified and protected (TECH FIG 1C).
- The interval between the sartorius and the vastus medialis is opened, exposing the superficial femoral artery and vein along with the saphenous nerve (TECH FIG 1D,E).
- The vessels and the saphenous nerve are dissected from proximal to distal and are reflected posterior and medial along with the sartorius muscle.
- All vessels (geniculates) are tied off with 2-0 or 3-0 silk ties as they course from the vessels toward the distal femur and tumor (TECH FIG 1F). The surgeon must not ligate the medial or lateral sural vessels, which are the main blood supply to the respective gastrocnemius muscles. These vessels are the basis of a gastrocnemius flap if required.
- The surgeon should be careful at the canal of Hunter because the vessels are just deep to the adductor tendon.
TECH FIG 1  •  A. Right leg with large secondary chondrosarcoma. B. A medial incision follows the sartorius proximally in the thigh to below the tibial tubercle. This allows immediate and very adequate visualization of the femoral and popliteal vessels. C. After the incision through the skin and subcutaneous tissue, a large posteromedial flap is developed deep to the fascia. The first vital structure identified and protected is the saphenous nerve. It accompanies the femoral vessels proximally in the thigh and follows the sartorius into the leg. Cutting the nerve results in numbness over the medial calf and occasionally a painful neuroma. D. In the middle and distal thigh, retracting the sartorius posteromedially exposes the superficial femoral vessels. E. In the proximal thigh, retracting the sartorius anterior and lateral allows exposure of the femoral vessels, all the way to the inguinal ligament if necessary. F. All vessels coursing toward the distal femur and tumor are tied with 2-0 or 3-0 silk sutures before they are cut. This minimizes blood loss, improves exposure, and guarantees the integrity of these structures. G. At the canal of Hunter, the adductor tendon is identified and cut. The main vessels are just beneath this structure, and care and patience at this point in the dissection are necessary. Several collateral vessels come off the femoral vessels at this point, coursing toward the femur and tumor. They need to be tied off. The saphenous nerve is seen accompanying the sartorius muscle.
Distal to the canal of Hunter the popliteal vessels are dissected free and reflected posterior and medially (TECH FIG 1G). The short head of the biceps muscle is now seen coursing proximal to distal to join the long head laterally in the thigh.

The sciatic nerve is exposed and protected.

Proximal and medial in the thigh above the tumor, the junction between the adductors and vastus medialis can be opened to the femur to reflect the quadriceps laterally off the femur (TECH FIG 2A).

Deep to the medial intermuscular septum is the terminal profunda artery and vein, which may be ligated.

The superficial femoral vessels, along with the saphenous nerve and popliteal vessels, are dissected free from the tumor throughout its length to below the joint line (TECH FIG 2B,C).

The medial gastrocnemius muscle can be incised. The surgeon must not ligate the medial sural vessels (TECH FIG 2D,E).

With the femoral vessels completely dissected and reflected, the quadriceps or a portion of it, along with the patella and patellar tendon, are now reflected over the tumor, leaving the vastus intermedialis as a very satisfactory oncologic margin.

Intra-articular resections are usually performed.

The joint capsule is opened and the anterior and posterior cruciate ligaments, the popliteus tendon, and the collateral ligaments are cut with an electrical cautery.

The posterior capsule is incised, with the popliteal vessels kept in direct view or under the operator’s finger to prevent injury.

A. Proximally in the thigh, above the tumor the adductor fascia meets the fascia of the vastus medialis. This interval is opened to permit exposure of the femur. The profunda vessels course just below the adductor fascia and follow the linea aspera. B. Saphenous nerve proximally in the thigh accompanies the superficial femoral vessels as the sartorius has been retracted posteriorly. The adductor tendon has not yet been cut, but the popliteal vessels have been exposed and mobilized to below the knee joint to guarantee their integrity. C. Completed medial dissection. The saphenous nerve follows the sartorius from proximal in the field. The femoral and popliteal vessels have been dissected and accompany the sartorius muscle and the saphenous nerve distally in the thigh. D. Medially at the knee, the medial gastrocnemius muscle is dissected and cut. E. Medial geniculaties are identified and cut. (continued)
TECH FIG 2 • (continued) F. An arthrotomy has been made. The quadriceps had been dissected and mobilized over the tumor mass, leaving the vastus intermedius muscle as an oncologic margin on the tumor. G. Cortical marks have been made on the femur and tibia above and below the planned resection levels to establish the length before resection that should be re-established with the reconstruction. The anterior cortical mark is placed at this time to help with rotation orientation.

- Intra-articular extension of the tumor is rare; when it occurs, it is covered with synovium. Local recurrence, when it occurs, is generally along the neurovascular dissection plane and not anterior in, or in the level of, the knee joint.
- The quadriceps is reflected over the tumor, leaving a cuff of muscle on top of the tumor as the oncologic margin. The vastus intermedius is left as an oncologic margin over the tumor (TECH FIG 2F).
- Cortical marks are as follows:
  - Before dislocating the knee, cortical marks are placed proximally on the femur and on the tibia, and the distance before resection is measured.
  - This distance should be the same after the prosthesis is implanted.
  - An anterior cortex is marked on the proximal femur to help with rotatory alignment during femoral stem insertion. This, along with the linea aspera, is used to determine appropriate rotatory position of the stem (TECH FIG 2G).
- The knee is dislocated and the short head of the biceps and the remaining posterior lateral capsule are cut.

Osteotomy and Preparation of the Femur, Tibia, and Patella

- The femur is cut with a saw at the predetermined level (TECH FIG 3A–C). One more centimeter than the assembled length of the femoral component is removed, and then only 7 mm is taken off the tibia. This 1.7 cm makes up for the distance between the prosthetic condyle and the undersurface of an 8-mm all-poly tibial component when assembled. This ensures leg-length equality (TECH FIG 4A). Alternatively, 17 mm can be taken off the tibia with jigs provided by the manufacturer, and the femur

TECH FIG 3 • A. The femur is cut with a Gigli or oscillating saw at the planned resection level and below the cortical marks. B,C. Anterior and posterior views of the specimen alongside the trial prosthesis.
can be cut exactly at the proximal level of the segmental component. While this may place the patella in a more anatomic location, it makes no difference in functional outcome (TECH FIG 4B).

- The proximal marrow is sampled and sent to pathology for frozen section analysis.
- The femur is reamed to accept the largest stem possible. This concept is “fit and fill.” Curved stems may add to rotatory stability. Stems smaller than 13 mm should be avoided in adults. The cut end is then chamfered (with a facing reamer) and cleaned with an irrigating brush (TECH FIG 4C–E).
- A proximal cement restrictor can be placed at this time if cement fixation is to be used.
- The tibia is osteotomized with an oscillating saw with a very slight posterior slope (TECH FIG 4F,G). This cut can

**TECH FIG 4** • A. With this author’s (JJE) technique, the femur is cut 1 cm longer than the planned femoral replacement. B. Only 7 mm is removed from the proximal tibia. This gives the largest platform for the tibial component. An 8-mm all-polyethylene tibial component is routinely used in primary reconstructions. The distance from the metal condyle to the inferior surface of an 8-mm poly tibial component is 1.7 cm. This ensures extremity-length equality to within millimeters. No effort is made to keep the patella right at the knee joint. Patellar tracking and postoperative function, which is what is important, are routinely excellent. C. After the marrow frozen section report has returned as negative for tumor, reaming the canal can commence, with the femur stabilized with a large locking clamp. Sharp reamers are used and the reaming is done slowly and gently, with copious irrigation to prevent a fat embolus. The canal is reamed to whatever level is necessary to permit the largest stem to fit easily. D. A chamfer reamer is used to prepare the osteotomy site. E. The canal is cleaned again slowly and gently with an irrigating brush. F. A freehand oscillating saw removes 7 mm from the upper tibia. Manufacturers now provide tibial cutoff instrumentation to permit the removal of larger amounts of tibia to keep the patella at the joint line. G. The tibial cut is usually perpendicular when the distal end points to the second metatarsal. The tibial cut should have a slight posterior slope to ensure full extension when the prosthesis is fully extended. If the slope is anterior, the patient will be left with a built-in flexion contracture. (continued)
be done freehand, though instrumentation is now available. Our routine is to take off only 7 mm, just below the cartilage. This leaves the largest surface area to support the reconstruction. An anterior slope will leave the final reconstruction with a knee flexion contracture. The proximal tibia is prepared to receive the tibia component. A distal bone plug or cement restrictor can be placed at this time. A trial all-poly tibial prosthesis is then inserted. An intraoperative radiograph is taken to ensure that the cut is perpendicular to the shaft and not in varus or valgus. The seating of the trial prosthesis is also determined to avoid varus or valgus tilt (TECH FIG 4H).

- The undersurface (50%) of the fat pad is removed to prevent impingement. This can be painful in the immediate postoperative period.

- The patella undersurface is removed and it is prepared (undercut with a burr) to receive the patellar component. One of the senior authors (MM) routinely resurfaces all patellas with a single central peg component. Alternatively, if the patella appears normal (as in most adolescents), there is no need to replace it (TECH FIG 4I–L).

- A trial reduction is made and a measurement is taken to be sure that the post-reconstruction distance is the same as the pre-resection distance (TECH FIG 4M).

- Range of motion is tested: the quadriceps and patella should track nicely without a tendency for lateral dislocation.

- A lateral release should be made at this time if there is a tendency for patellar subluxation or dislocation.

- The tension of the superficial femoral vessels is also checked. The distal pulses at the ankle are checked with a Doppler with the reconstruction in full extension. Overlengthening can cause excessive tension and compression of these structures.

- Overlengthening should be avoided. It is harder to rehabilitate a lengthened extremity. Leg-length inequalities in the growing child can be made up at a later date with an exchange of one of the segmental modules rather than overlengthening at the time of the initial resection. Some adolescent patients never need a lengthening. Overlengthening also increases the risk of sciatic or peroneal nerve palsy.

### Selection and Placement of the Components

- The patellar component should not overhang the cut surface of the patella. A central peg poly component is used and the surface of the bone is undercut to aid in fixation. The rationale for resurfacing the patella is that it allows immediate and vigorous rehabilitation without concern that any knee pain may be due to the patellar cartilage grinding on the metal distal femoral prosthesis. This is more important given that the goal is an active range of motion of 120 to 130 degrees of
flexion, full extension, and no extensor lag. This is routinely achieved. If the expectation of active knee motion is 90 degrees or less, then it probably does not make any difference whether the patella is resurfaced or not.

- The all-poly tibia is almost always 8 mm in primary cases. Metal-backed tibial components are not necessary in primary cases but are routinely used in revisions.
  - The tibial poly is oriented to face the tibial tubercle (slight external rotation).
- The femoral component is picked to maximize the “fit and fill” concept and is oriented anatomically based on the anterior cortical mark and the linea aspera.
- The actual components are assembled on the back table and another trial reduction is performed to check lengths, the tension of the vessels, and distal pulses as well as tracking of the patella. All of the tapers must be dry before impaction, because a “wet” taper will cause unlocking or disassociation.

Cementing of Components

- All components are cemented.
- Before cementing, 100 mg of hydrocortisone (Solu-Cortef) is given intravenously to protect against fat embolism. The deleterious effects of a fat embolism are due to a massive inflammatory response in the lungs. Steroids are the best anti-inflammatory agent.
- Antibiotic-impregnated cement is routinely used.

- The tibial component and the patella are cemented first.
- The cement is injected while it is still fairly liquid, and the femoral canal is pressurized.
- The femoral stem is inserted slowly. Rapid insertion can lead to a fat embolism.
- Once the stem is placed, rotatory changes are avoided because they will lead to poor fixation and early loosening. No last-minute adjustments should be made on the femoral side.
- A final measurement is made once the final components are in place.
- The final reconstruction with and without the resected specimen can be seen in TECH FIG 5A,B.

Closure and Postoperative Care

- Before closure, homeostasis should be meticulous.
- The wound is irrigated copiously with antibiotic solutions, with all final rinses with saline solutions.
- The joint capsular tissue is closed to the remaining capsular tissue about the proximal tibia.
- The sartorius is sutured to the vastus medialis over a deep 10-mm flat drain with a #1 absorbable suture (TECH FIG 6).
- The subcutaneous tissue is closed over a superficial 10-mm flat drain.
- The drains are sutured in place and are kept in place until the 24-hour drainage is less than 30 to 40 cc per hour.
- Skin closure can be with staples or a subcuticular suture.
- Gastrocnemius flaps are necessary in less than 1% of cases but can be useful to cover an endoprosthesis if adequate tissue is not available. More common use of the gastrocnemius flap reflects an individual surgeon’s resection philosophy and technique.
- Sterile dressings and an Ace wrap are applied.
- The patient is placed in the bed with a continuous passive motion machine, flexing to 30 degrees and extending to −5 degrees for 3 days. The range of motion is then advanced rapidly to achieve 90 degrees of flexion before discharge.
- Sequential compression boots are applied to the feet.
- The next technique, from an anterior (transadductor) approach, may be used as an alternative.

RESECTION AND RECONSTRUCTION OF THE DISTAL FEMUR THROUGH A LONGITUDINAL LATERAL APPROACH AND PREPARATION FOR CEMENTING THE TIBIA, PATELLA, AND FEMORAL COMPONENTS

- Indications for the lateral approach:
  - All revision cases
  - Total femur reconstructions
  - Primary distal femoral tumors that extend so far proximally that cross-pin stem fixation, either at 90 degrees to the shaft or 135 degrees into the femoral neck, is necessary to achieve a stable reconstruction.  
  - Patient preparation for the lateral approach is identical to the medial approach.
  - Once anesthesia is administered, the urinary catheter is placed, and the vancomycin and gentamicin are administered, the patient is rolled to the lateral decubitus position, with all pressure points carefully protected.
  - The entire leg is draped and prepared, from above the iliac crest to the foot.
  - A tourniquet is not used.
  - A longitudinal lateral incision is made from the tibial tubercle to as far proximal as necessary. It can be extended to the tip of the trochanter and then on to the anterior superior iliac spine if a total femur endoprosthesis is planned.
  - The skin and subcutaneous tissues are incised with an electrical cautery knife. The fascia lata is incised in line with its fibers.
  - The lateral intermuscular septum is identified and the entire vastus lateralis can be released from its posterolateral insertion after tying all the perforators before cutting them. Then the entire vastus lateralis can be flipped up over the femur, exposing the entire length of the bone. A cuff of muscle can be left on the tumor as oncologic needs dictate.
  - Because the tibial tubercle is a somewhat laterally placed structure, care needs to be taken to avoid avulsion of the patellar tendon.
  - The remainder of the procedure is identical to the medial approach.

ANTERIOR (TRANSADDUCTOR) APPROACH TO THE DISTAL FEMUR AND POPLITEAL SPACE FOR RESECTION OF TUMORS OF THE DISTAL FEMUR AND ENDOPROSTHETIC RECONSTRUCTION

- The traditional approaches to the distal femur are medial and anteromedial. These techniques facilitate access to the anterior aspect of the femur and allow exploration of the popliteal fossa and mobilization of its neurovascular structures by developing large fasciocutaneous or subcutaneous flaps (TECH FIG 7).
- Because some of the blood supply to the skin and subcutaneous tissue is inevitably compromised during the development of the flaps and because all the geniculate vessels are routinely ligated as part of the resection of the distal femur, the risk for ischemic flap necrosis is increased. In addition, separating the vastus medialis from its fascia and subcutaneous tissue compromises the vascularity of the outer layer of the muscle. Consequently, resection of the inner portion of the vastus medialis, which often is oncologically necessary, compromises the vitality of its residual outer layer and often prevents adequate soft tissue coverage of the endopro-
The distal aspect of the VM is developed. D. The surgical approach shown in A–C. E. The vastus intermedius tendon is opened and the medialis is mobilized. F–H, K. The termination of the sartorial canal containing the superficial femoral artery and vein is dissected free. H. The sartorial canal has been opened. I. The remaining attachment of the adductor magnus tendon to the distal femur is released. J. Relationship of the superficial femoral artery to the popliteal space and the adductor magnus tendon. (continued)
If minimal muscle coverage remains a problem after resection and attempted closure, the sartorius muscle can be rotated to cover small defects. In addition, a formal sartorius muscle transfer can be performed through this incision to recreate or to replace either partial or complete vastus medialis loss.

**Position and Incision**
- With the patient in the supine position and the surgeon standing on the medial side of the knee (opposite side of the table), a long, medial paramedian skin incision is made. The incision extends proximally along the junction of the rectus femoris and vastus medialis muscles and curves distally around the medial border of the patella to the level of the pes anserinus.

**Proximal Interval and Creation of Musculocutaneous Flap**
- The interval between the rectus femoris and vastus medialis muscles is identified and opened to expose the underlying vastus intermedius muscle. The fibers of the vastus intermedius are then carefully divided. It is important not to separate the overlying muscle from its fasciocutaneous coverage, which would defeat the purpose of this approach. This can be ensured by suturing the vastus medialis to the overlying skin.

**Exposure of Intermuscular Septum and Adductor Hiatus**
- The plane between the vastus medialis and the medial femoral condyle is identified distally (similar to the subvastus approach). The vastus medialis muscle is dissected off the medial femoral condyle in an extra-articular fashion and retracted medially, away from the knee capsule. By sweeping the fibers of the muscle from the intermuscular septum with a sponge, the intermuscular septum, the adductor hiatus, and the adductor magnus tendon are exposed.

**Identification of the Superficial Femoral and Popliteal Vessels**
- The sartorius muscle, which crosses over the proximal portion of the vastus medialis, is mobilized posteriorly by opening the thin fascia between the vastus medialis and its superior border. The superficial femoral artery and vein are identified proximally at the level of the adductor hiatus. With the surgeon’s finger placed into the adductor hiatus to protect the underlying vessels, the distal portion of the adductor magnus tendon is dissected and released from the distal femur and adductor tubercle, partially exposing the popliteal space. The superficial femoral vessels are carefully dissected and mobilized along their sheath, and vessel loops are placed around them as they enter the popliteal fossa.

**Completion of Popliteal Exposure**
- The knee is placed in 90 degrees of flexion. With the vastus medialis musculocutaneous flap retracted posteriorly, the entire popliteal space is visualized and the popliteal vessels are identified distally between the two heads of the gastrocnemius muscle. After the identification of the
popliteal vessels, the medial head of the gastrocnemius is released from the femoral condyle; this should be performed with the surgeon’s finger placed underneath the muscle, protecting the popliteal artery and vein. In addition, care should be taken to preserve the medial sural artery, which is the sole vascular supply to the medial head of the gastrocnemius (TECH FIG 8).

Mobilization of the Popliteal Vessels and Sciatic Nerve

- Mobilization of the popliteal vessels is facilitated by individually ligating their geniculate branches from the level of the adductor hiatus to the junction of the gastrocnemius muscle. A downward traction maneuver of the vessels allows better identification of the geniculate branches.
- The sciatic nerve is then exposed over the proximal portion of the popliteal fat and followed distally to its bifurcation into the tibial and common peroneal nerves. The popliteal vessels are then covered by a sponge soaked in papaverine to prevent potential vasospasm.

Lateral Structures Release

- After complete exposure of the popliteal space, including release of the medial head of the gastrocnemius and mobilization of the popliteal vessels, the lateral head of the gastrocnemius muscle, the short head of the biceps muscle, and the entire posterior capsule are released.

Anterior (Intra-articular) Release and Distal Femoral Osteotomy

- To complete the soft tissue dissection of the distal femur, the anterior capsule is opened transversely and both cruciate ligaments are divided. With the superficial femoral vessels mobilized, the femoral osteotomy, which is usually made 15 to 20 cm proximal to joint line, above the level of the adductor hiatus, can now be safely performed. The following steps to complete the resection and reconstruction are identical to those discussed above:
  - Intra-articular resections
  - Cortical marks
  - Osteotomy and preparation
  - Trial reduction
  - Selection and placement of the components
  - Cementing
  - Closure

Medial Gastrocnemius Muscle Transfer

- The medial gastrocnemius muscle is the mainstay of muscle transfers of the distal femur. The technique of medial gastrocnemius transfer for difficult and complicated distal...
Femoral resections was initially described by Malawer and Price in 1985 (Tech Fig 9).

- This muscle transfer provides excellent coverage for small and large medial and anterior defects after distal femoral resection. It has been our experience that a free flap has never been required after distal femoral resection and endoprosthetic replacement.

- The medial gastrocnemius muscle is dissected free of its tendinous and midline insertions in the calf after cementing of the prosthesis. It may then be rotated transversely or proximally, depending on the area to be covered. Usually the skin can be closed directly over the transferred muscle, but if there is any skin tension or swelling, the skin flaps are sutured directly to the muscle transfer and the remaining defect is closed with a split-thickness skin graft onto the muscle directly at the time of surgery.

- There is a thick fascia covering both the anterior and posterior surfaces of the medial gastrocnemius muscle. These fascia coverings are routinely removed with a sharp blade. This permits the muscle to expand about 150% larger than normal. The muscle can then be rotated either proximally to cover large medial defects or anteriorly to cover the entire exposed knee joint. The arc of rotation may be increased by releasing the sartorius and the other pes muscles. These muscles are then tenodesed to the transferred gastrocnemius muscle after rotating the gastrocnemius into place.

- The medial gastrocnemius muscle is fed by one major branch: the medial sural artery off the popliteal artery. The origin of this branch is at or below the knee joint line. At the time of popliteal exploration and dissection, it is essential to preserve this branch and not mistake it for a geniculate vessel. Geniculate branches pass anterior from the popliteal artery, whereas the medial sural artery passes posterior and medial. This vessel usually takes off at about the level of the inferior geniculate pedicle. The lateral gastrocnemius is rarely used because it is a much smaller muscle and its arc of rotation is decreased by the peroneal nerve and the fibula.

**Pain Control**

Silastic epineural catheters are routinely placed (MM) in the femoral nerve sheath and a 10-cc bolus of 0.25% bupivacaine is infused before the patient is transferred to the recovery room. Four to 8 cc per hour is administered using an infusion pump for up to 72 hours postoperatively. This provides excellent pain control and decreases systemic narcotic requirements by more than 50% (Tech Fig 10).
POSTOPERATIVE CARE

- In the operating room the patient is placed in the bed with a continuous passive motion machine, flexing to 35 degrees and extending to –5 degrees. That range of motion is maintained until the third day, when it is advanced 10 to 15 degrees a day to achieve 90 degrees before discharge.
- The inpatient stay is generally 7 to 10 days.
- A towel roll is placed under the heel three times a day for 60 minutes to ensure that full extension is achieved and that a flexion contracture is avoided. This practice is continued for the first 4 weeks after surgery.
- The patient is mobilized out of bed on the third postoperative day and ambulated initially with a walker and then crutches and with a knee immobilizer, which is kept on for 4 to 8 weeks when out of bed.
- Before discharge the patient should be able to flex to 90 degrees and do 10 straight-leg raises with the knee immobilizer on, should be in and out of bed independently, and able to go up and down stairs.

- The drains are removed when the drainage in a 24-hour period is less than 30 to 40 cc in each drain; generally this is in 5 to 6 days.
- Intravenous antibiotics are continued until the drains are removed.
- Anticoagulation after surgery is based on the patient’s risk factors.
- A circumferential compression Ace wrap is used for 2 months, and sometime a Neoprene knee brace is used for several months.
- Outpatient physical therapy is begun 4 to 6 weeks after surgery and lasts for 12 weeks. The goals are to maximize knee flexion, motor strength, and gait. Most patients achieve more than 120 degrees of flexion, have full extension without a lag, and walk without a limp. By 4 months the patient should be able to walk down the hall and most observers would not be able to tell that he or she has had surgery.
### PEARLS AND PITFALLS

| Difficulty closing the wound | Difficulty in wound closure usually occurs as a result of significant muscle resection due to the oncologic need for adequate margins. A too-long leg can cause this problem. The level of the patella should be checked. A medial gastrocnemius muscle flap should be used if there is any question about the viability of the medial closure or if a significant amount of the vastus medialis has been resected. Occasionally, the sartorius muscle can be rotated to close a small defect instead of the gastrocnemius muscle. |
| Identifying surgical planes medially and the subvastus interval | The surgeon should carefully identify the vastus medialis and rectus femoris interval and the subsequent vastus intermedius below it. The vastus medialis is mobilized extra-articularly from the femoral condyle. |
| Mobilization of the superficial femoral vessels | These vessels are identified within the sartorial canal and traced to the adductor hiatus. The surgeon places a finger into the hiatus before releasing the adductor fibers and intermuscular septum. |
| Difficulty identifying the popliteal vessels, especially distally | The surgeon should release the medial gastrocnemius muscle within 1 to 2 cm from its insertion onto the medial condyle. The popliteal vessels are found between the two heads of the gastrocnemius muscles. |
| Injury to or ligation of the medial sural artery | The medial sural artery is the main pedicle to the medial gastrocnemius muscle. This branch comes off medial and posterior from the popliteal artery. The geniculates take off anteriorly. The surgeon must not ligate any “geniculate” if it appears to be running medial or posterior. |
| Injury to the sciatic nerve, especially the peroneal branch | The sciatic nerve is easily identified in the popliteal space covered by fat posterior to the popliteal vessel sheath. These two sheaths are separate in the proximal portion of the popliteal space. Only after the sciatic nerve divides does the tibial nerve join the popliteal vessels within a common sheath. The peroneal nerve runs lateral to exit the popliteal space and runs lateral to the lateral gastrocnemius muscle. The nerve can easily be injured at this level, especially when the lateral gastrocnemius is released from the femoral condyle. |
| Injury to the popliteal artery and vein | Although these vessels are initially identified and mobilized, they can be iatrogenically injured later in the procedure. The surgeon must be careful when releasing the posterior capsule. The popliteal vessels are tied down to the capsule at the joint line by the most inferior geniculate vessels. These vessels should be ligated early in the procedure so that the popliteal vessels fall away from the entire femur and capsule. Occasionally the popliteal vessels are punctured by the distal end of the osteotomized femur. The surgeon should pack off the distal femur with a laparotomy pad to avoid this. |
| Absent pulses after closing the wound | This is most common in young patients with small-diameter vessels. It is often due to severe vascular spasm, usually secondary to small vessels, long length of vessels exposed, and exposure to the cold operating room air. It is best to avoid this situation by placing papaverine (vasodilator)-soaked sponges and warm laparotomy pads on the vessels throughout the procedure. If this does occur, the surgeon must ensure that the vessels are intact and not kinked off or thrombosed secondary to traction, intimal damage, or iatrogenic ligation. An intraoperative angiogram and a vascular surgeon consultation should be obtained. In most cases, the wound should be opened and the popliteal vessels quickly explored. The vascular surgeon may choose to pass Fogarty catheters to make sure there is no thrombus, but this technique is also a good means of opening a severely spasmed artery. |
| Unequal leg lengths | Taking careful measurements before resection and after implantation ensures leg-length equality to within millimeters. |
| Fitting and filling the femoral canal | Ream up the femoral canal to maximize fit. |
| Tying vessels before cutting | Tying vessels before cutting minimizes blood loss and improves visibility. |
| Cementing all components, including the patella and all-poly tibia | We have had no patellar or proximal tibia poly failures in 25 years. Cementing permits aggressive rehabilitation. |
| Preventing fat embolism | Ream the canal slowly, insert the stem slowly, and pretreat with 100 mg of hydrocortisone (Solu-Cortef) before cementing. |
| Preventing patellar dislocation | Ensure soft tissue balance; perform a lateral release if necessary before closure. |
| Unwillingness to plan for and do the revisions | A surgeon unwilling to plan for and do revisions should probably not be doing the primary resections and reconstructions. |
OUTCOMES

- In a study by Bickels et al,110 patients diagnosed between 1980 and 1998 with lesions of the distal femur underwent distal femur resection and endoprosthetic reconstructions. Extra-articular resection of the knee occurred in only two of these patients, both of whom were diagnosed with a primary bone sarcoma with tumor extension into the knee along the cruciate ligaments.
- Reconstruction implants included 73 modular prostheses, 27 custom-made prostheses, and 10 expandable prostheses. Only eight patients had a constrained knee mechanism (earlier edition); the remaining patients had reconstruction with a rotating-hinge knee mechanism prosthesis. Twenty-one medial, three lateral, and one bilateral gastrocnemius flaps were used after resection for soft tissue reconstruction. Ten patients with expandable prostheses had 14 lengthening procedures performed.
- Patients who had reconstruction with a rotating-hinge knee mechanism were more likely to have a good to excellent functional outcome (91%) than those who had reconstruction with a constrained knee mechanism (50%).

COMPLICATIONS

- Complications in the above study included six deep wound infections (5.4%), three of which resulted in amputation, two prosthetic revisions, and one wound débridement. Overall, there were 15 revision surgeries; they entailed replacement of a failed polyethylene component in six patients and prosthetic revision in nine patients (aseptic loosening, six; deep infection, two; radiation bone necrosis, one) (FIG 9).
- Two of the polyethylene component failures occurred in the same patient; the first occurred 2.5 years after the initial surgery and the second occurred 3.8 years later. Polyethylene failures occurred after an average of 3.7 years (range 1.25 to 7.25 years) and aseptic loosening occurred after an average of 5.5 years (range 3.2 to 10.3 years).
- During revision of their prostheses, all patients who underwent additional surgery because of a loosened prosthesis were found to have concomitant failure of a polyethylene component.

Local Recurrence

- The risk of local recurrence is surgeon-dependent. It occurs independent of the type of reconstruction (arthrodesis, allograft, or endoprosthesis).

Infections

- Infections are related to the local environment at surgery, bacteremias in the immediate postoperative period, length of the surgery, and soft tissue coverage problems. Infections are also generally independent of the type of reconstruction, though the rate is significantly higher in allograft reconstructions (FIG 10).
- Twenty-five to 30% of deep periprosthetic Staphylococcus aureus or Staphylococcus epidermidis infections can be salvaged.

FIG 9 • Survival of the distal femoral prosthesis. Kaplan-Meier curves of prosthetic survival. A. Custom versus modular prosthesis survival for all anatomic sites. The difference is mostly due to changes in surgical technique and reconstruction of the soft tissues. B. Endoprosthetic survival versus actual patient survival. The prosthesis is extremely reliable over the patient’s lifetime. C. Survival of all distal femoral prostheses. D. Prosthetic survival by various anatomic sites.
if treated early with aggressive and radical débridement, including prosthesis removal, implantation of antibiotic-impregnated cement spacers, and 6 to 8 weeks of intravenous antibiotics, followed by reinsertion of the components if aspirations are negative. Most other bacterial infections and all the gram-negative infections are difficult to cure and can lead to amputation.

- An exposed prosthesis is another cause of infection. Although needed infrequently by one author (JJE), rotation flaps and free flaps have been advocated and used to solve this problem. Their frequent application in primary cases reflects the individual surgeon’s resection philosophy and techniques.3

Fat Embolism

- Fat embolism can result from a number of factors, alone or in combination. Reaming the canal should be done slowly and gently with sharp reamers and frequent irrigation and suction. Although cement restrictors and pressurization of the cement are regularly used, stem insertion is again done gently and slowly. Patients should be well hydrated and oxygenated before insertion of cemented femoral stems.
- Fat emboli cause a massive inflammatory reaction. Because steroids are the best anti-inflammatory medication, 100 mg of hydrocortisone (Solu-Cortef) is routinely administered before cementing and insertion of long intramedullary stems.
- Massive fat emboli can be fatal.

Mechanical Failures

- Mechanical failures includes fatigue fracture of any endoprosthetic metal or polyethylene component, aseptic loosening, disassociation of modular components, and polyethylene wear synovitis (FIG 11).
- Most mechanical failures can be revised. The key to success is to analyze the failure mode and not do the same reconstruction. Although the literature suggests that revisions have a 50% failure rate at 5 years, if you analyze the failure mode and correct it, the revision should last longer than the original reconstruction.13
- The rotating-hinge knee was introduced in December 1980 and has become the international standard knee mechanism for distal femoral knee reconstructions. Anteroposterior stability and mediolateral stability are built into the mechanism, which permits complete resection of all the knee ligaments, a necessity in all tumor resections. The capacity to rotate slightly with loading defuses stress at the bone–prosthesis or the bone–cement–prosthesis interfaces, diminishing aseptic loosening and fatigue fracture.6
The development of modular components with forged stems has greatly reduced the incidence of fatigue fracture, especially of the femoral stems, compared with casted stems. This is unless there is a mismatch between the patient size and the implant size: an 11-mm stem in a 250-pound patient is a recipe for failure.

**Bushing Failures and Pseudomeniscus Formation**

- Bushing failures are heralded by the sudden onset of knee joint pain and a sense of instability to the point that ambulatory aids are necessary. Only on rare occasions, when there is complete disintegration of the bushing and extensor stop, will the radiographs be positive with medial or lateral protrusion of the axle. Surgical exploration, therefore, is done because of a high index of suspicion. This tends to be a late complication: the median time to failure in a series of seven cases was 84 months (range 30 to 112 months; **FIG 12**).

**FIG 12** • **A.** Breakage of medial bushing. **B.** Close-up of residual bushing. **C.** Delamination of a bushing and bumper. **D.** Delamination of a poly bumper removed 17 years after surgery. **E.** Clinical photograph showing gross instability to a varus stress test. This instability is characteristic of worn or broken bushings. **F, G.** Patients with pseudomenisci present with localized pain, lack of full extension, and no effusion. **H.** Gross specimen of a pseudomeniscus. This is formed by thick fibrous collagen without an inflammatory component. Pseudomeniscus rarely occurs before 5 to 7 years after surgery.
Pseudomeniscus and Internal Derangement of the Knee
- The term “pseudomeniscus” refers to scar tissue formation between the moving components of the femoral condyles on the tibial bearing component as well as under this component and the cemented all-poly (within the tibia). Scar tissue over time and with constant motion will form a true fibrocartilage type of scar that takes the shape of a true meniscus.
- Pseudomeniscus formation occurs frequently but is symptomatic in only a few patients. The symptoms are usually subtle, often presenting as an internal derangement of the knee. The most suggestive signs are a feeling of instability, combined with slight valgus instability (more than 5% on a stress test), and with or without a small effusion. There are no real diagnostic tests. Suspicion is the key to diagnosis. These symptoms may mimic those of a bushing failure, but with less instability and a smaller effusion.
- The true incidence of symptomatic pseudomeniscus is 5% to 7%. The treatment is resection of the pseudomeniscus as well as the pseudocapsule in the hope of preventing a recurrence.

Stem Fracture
- The incidence of femoral stem fractures has been reduced significantly with the introduction of forged stems, but they can occur, especially if the stem is undersized compared to the weight of the patient. Stem loosening usually precedes catastrophic fatigue fractures and may present as an actual displaced bone fracture.
- If the stem cracks but does not displace, the patient will have pain at the site of fracture, but the radiographs will remain negative until enough motion exists to cause displacement of the metal fracture pieces. Pain is significant and the patient will seek ambulatory aids. The older casted stems tended to break about 2 cm proximal to the forged junction with the body.

Disassociation of Morse Tapers
- Disassociation of the Morse taper locking mechanism is exceedingly rare and most likely due to failure to impact the components adequately. Surgical exploration and reassembly of the components and full impaction are required.

Aseptic Loosening
- The incidence of aseptic loosening of the femoral stems has been reduced by the incorporation of extramedullary porous ingrowth beads at the junction of the segmental replacement and the stems. Soft tissue ingrowth into these beads in the diaphysis isolates the joint debris from the bone–cement–prosthesis composite, creating a “biologic purse-string” effect. Hydroxyapatite coatings can also enhance fixation.
- Cross-pin stem fixation requires a custom component but permits the use of a short stem or a metaphyseal position that would normally lead to early aseptic loosening.
- On rare occasions patients develop a polyethylene debris synovitis. Exploration of the reconstruction, resection of the “pseudosynovium” or periprosthetic capsule, and exchange of the bushings and extensor stop can manage this. JE never revises the all-poly tibia or poly patellar components if they are well cemented unless there is an infection. If the cemented tibial poly is removed, then at reconstruction a metal-backed tibial component is used. Recementing an all-poly tibia component in revision situations risks early aseptic loosening, as the cementation is never as good as the primary reconstruction.

REFERENCES
BACKGROUND

- Resection of the proximal tibia includes the removal of one half to two thirds of the tibia along with a portion of all muscles that insert on it, as well as the entire popliteus muscle, in combination with an extra-articular resection of the proximal tibiofibular joint. The peroneal nerve is preserved.
- Of all anatomic locations in which major bone resections and prosthetic reconstructions are done, the proximal tibia is considered to be the site in which surgery is the most complicated, where rates of complications are highest, and whose functional outcome is poorest. The major reasons are the lack of muscle coverage along the anteromedial aspect of the tibia, the relatively small caliber of the blood vessels around the leg, and the need to include the insertion site of the extensor mechanism in the removed surgical specimen. In the past, these difficulties made it impossible to perform limb-sparing surgery, and above-knee amputations were the only surgical option for malignant tumors at this site.
- The limb-sparing technique illustrated in this chapter offers a safe approach to the dissection of popliteal vessels and to the resection and replacement of the proximal one third to two thirds of the tibia. Preoperative evaluation of tumor extent requires a detailed understanding of the anatomy and careful evaluation by CT, MRI, bone scintigraphy, and biplane angiography.
- Types of possible reconstructions include primary arthrodesis, prosthetic replacement, and allograft replacement. We prefer prosthetic replacements because of the high rates of nonunion and infections associated with allograft reconstruction and the poor function of an arthrodesed knee. The use of a gastrocnemius rotational flap is a key factor in achieving adequate soft tissue coverage of the prosthesis and in restoring function of the extensor mechanism.

ANATOMY

Knee Joint and Cruciate Ligaments

- The knee joint is seldom directly invaded by tumors of the proximal tibia. When it does occur, invasion is usually the result of a pathologic fracture, contamination due to improper biopsy technique, or tumor extension along the cruciate ligaments. The presence of hemarthrosis is suggestive of intra-articular disease.
- Involvement of the cruciate ligaments is often not determined until the time of surgery, although an MRI is a reliable means of determining cruciate ligament involvement preoperatively. An extra-articular resection (ie, en bloc resection of the proximal tibia, joint capsule, and femoral condyles) should be considered if nodules are identified on the cruciate ligaments.

Extensor Mechanism

- The attachment site of the extensor mechanism at the tibial tuberosity is resected en bloc with the proximal tibia. Reconstruction of this mechanism is essential for a functioning extremity.

Popliteal Trifurcation

- The popliteal artery divides into the anterior tibial artery, the posterior tibial artery, and the peroneal artery at the inferior border of the popliteus muscle. The popliteal trifurcation is actually composed of two bifurcations. The first is found where the anterior tibial artery arises from the popliteal artery, which then continues as the tibioperoneal trunk. The anterior tibial artery, the first branch, arises at the inferior border of the popliteus muscle.
- The second bifurcation is found where the peroneal artery and the posterior tibial artery arise from the tibioperoneal trunk; thus, this bifurcation is distal to the anterior tibial takeoff. It is almost always necessary to ligate the anterior tibial artery at the time of resection, while the other vessels must be identified before ligation.
- A unique and fortuitous anatomic feature is that the popliteus muscle covers the posterior surface of the tibia, which affords an excellent boundary between the posterior soft tissue extension from the tibia and the neurovascular bundle of the lower extremity. This is in contrast to what occurs at the distal femur, in which the posterior aspect is covered solely by the popliteal fat.

Tibiofibular Joint

- The proximal tibiofibular joint is located close to the posterolateral aspect of the proximal tibia. Histologic studies show that tumors involving the proximal tibia have a high incidence of extension and involvement of the periscapular tissues of the tibiofibular joint.
- To obtain a satisfactory surgical margin while performing a resection of the proximal tumor, it is necessary to remove this joint en bloc (ie, perform an extra-articular resection). This is a routine procedure for all high-grade sarcomas of the proximal tibia.

Subcutaneous Location of the Tibia

- The entire medial aspect of the tibia lies in a subcutaneous location and remains there after resection and reconstruction approaches had been carried out. This had been a major source of primary and secondary infections, which, in turn, frequently necessitated above-knee amputation.
- Today, the routine transfer of the medial gastrocnemius muscle anteriorly, to cover the prosthesis, is considered a reliable method of prosthetic coverage and one that also provides a method of extensor mechanism reconstruction. It is a simple and reliable means of decreasing the incidence of infection, flap necrosis, and secondary amputation.

INDICATIONS

- Primary bone sarcomas of the proximal tibia (FIG 1A,B)
- Benign-aggressive tumors associated with extensive bone destruction (FIG 1C-G)
- Metastatic tumors associated with extensive bone destruction
The major contraindications to limb-sparing surgery are neurovascular involvement and compromise as well as extensive soft tissue tumor involvement that precludes adequate prosthetic coverage.

IMAGING AND OTHER STAGING STUDIES (FIG 2)

CT and MRI
- CT and MRI are useful to determine the extent of cortical destruction and intramedullary and soft tissue extensions of the primary tumor. These data are essential for determining the level of tibial resection, which is 3 to 5 cm distal to the area of intramedullary tumor involvement.
- MRI can also reveal skip lesions, which may affect the extent of tibial resection.

Angiography
- Biplane angiography (FIG 3) is used for local arterial evaluation, especially if CT has revealed posterior soft tissue extension. The anteroposterior view is used to evaluate the popliteal bifurcation; of particular relevance is the integrity of the posterior tibial artery, which may be the sole blood supply to the leg after resection.
The lateral view is essential for evaluating the interval between the tibia and the neurovascular bundle. For example, the popliteus muscle often separates a posterior tumor mass from the vessels. This is reflected as a clear interval on the lateral angiogram and serves as an indication that there is an adequate resection margin.

- Ligation of the anterior tibial artery is almost always required.
- The peroneal artery may be involved by tumors that have a large posterior compartment. Two of the major vessels may be ligated in a young patient without jeopardizing the possibility of a viable and functional extremity.

**SURGICAL MANAGEMENT**

- There are three major steps involved in successful resection and reconstruction of tumors of the proximal tibia:
  - Resection of the tumor
  - Prosthetic reconstruction of the skeletal defect and knee joint
  - Reconstruction of the extensor mechanism and soft tissue coverage of the prosthesis with a gastrocnemius flap\(^1,3\)

---

**FIG 2** • AP (A) and lateral (B) plain radiographs, computed tomography (C), and magnetic resonance (MR) imaging (D) showing osteosarcoma of the proximal tibia. These studies show that the tumor is associated with minimal destruction of the cortices and that there is no soft tissue extension. The MR scan also accurately depicts the distal point of the intramedullary tumor extension. These findings will assist in determining the osteotomy level and the amount of surrounding soft tissue to be resected en bloc with the tumor. AP plain radiograph (E) and computed tomography (F) showing osteosarcoma of the proximal tibia with cortical destruction and soft tissue extension of stage IIB osteosarcoma.
**FIG 3** • An angiogram showing a lateral view of the popliteal artery. The space between the tumor in the proximal tibia and the popliteal bifurcation is best visualized by this study. The popliteal artery (P), tibioperoneal trunk (TP), and anterior tibia (AT) arteries are all identifiable. The soft tissue posterior to the tumor mass (curved arrow) must be free of cancer along the popliteal artery and tibioperoneal trunk. The popliteus muscle covers the bone in this interval and usually protects the vessels from tumor invasion. A tumor (T) blush (small arrows) is seen anteriorly. (Reprinted with permission from Clin Orthop Relat Res 1989;239:231–248.)

**INCISION**

- A single anteromedial incision is made, beginning proximally at the distal third of the femur and continuing to the distal third of the tibia. The approach includes excision of biopsy sites with a margin of at least 2 cm. Medial and lateral thick flaps of skin and subcutaneous tissue including the fascia are developed to decrease the likelihood of flap ischemia (TECH FIG 1).

**TECH FIG 1** • Illustration (A) and photograph (B) showing the anteromedial incision used for exposure of the proximal tibia and neurovascular bundle. It begins at the distal third of the femur and continues to the distal third of the tibia, and includes excision of the biopsy site, which remains attached to the underlying bone. C. Thick fasciocutaneous flaps are developed. (A: Reprinted with permission from Clin Orthop Relat Res 1989;239:231–248.)
EXPLORATION OF THE POPLITEAL FOSSA AND DETACHMENT OF THE VASCULAR BUNDLE

- The popliteal trifurcation must be explored early to determine whether the tumor is operable, especially if its soft tissue component extends posteriorly. The popliteal space and trifurcation are exposed by detaching the medial gastrocnemius muscle and by splitting the soleus muscle (TECH FIG 2A–C).

- The popliteal artery can be easily identified and it can be traced distally around the popliteus muscle. Care must be taken to identify and protect all major vascular branches.

- Applying posterior traction proximal to the popliteal artery permits visualization of the takeoff of the anterior tibial artery and its accompanying veins. The anterior tibial vessels are individually ligated, allowing the entire neurovascular bundle to fall away from the posterior aspect of the tibia or tumor (TECH FIG 2D).

- If the mass is a large one, the peroneal artery may need to be ligated as well, leaving the posterior tibial artery as the single blood supply to the leg. Further posterior mobilization of the popliteal vessels is achieved by ligation of the inferior geniculate vessels.

TECH FIG 2 • Illustration (A) and operative photograph (B) showing exploration of the popliteal artery trifurcation, which is required to determine the feasibility of resectability. The medial flap is continued posteriorly, and the medial hamstrings are released 2 to 3 cm proximal to their insertion to expose the popliteal fossa. The popliteal vessels are identified, and the trifurcation is initially explored through the medial approach. The medial gastrocnemius is partially mobilized, and the soleus muscle is split to expose the neurovascular structures. Care is taken to preserve the medial sural artery, which is the main pedicle to the medial gastrocnemius muscle. If the interval between the posterior aspect of the tibia and the tibioperoneal trunk (separated by the popliteus muscle) is free of tumor, resection can proceed. C. Dissection and exposure of the neurovascular bundle is often difficult because the tumor has distorted the normal anatomy. It requires splitting of the soleus muscle for most of its length. Care should be taken to identify and protect all major vascular branches before any ligation. The anterior tibial artery, which is the first takeoff of the popliteal artery, is located at the inferior border of the popliteus muscle. As it passes directly anterior through the interosseous membrane, it tethers the entire neurovascular bundle. D. Ligation of the anterior tibial vessels allows the entire neurovascular bundle to fall away from the posterior aspect of the tibia. (A,C,D: Reprinted with permission from Clin Orthop Relat Res 1989;239:231–248.)
The capsule is transected circumferentially about 1 cm away from the tibia and the patellar tendon to avoid contamination (TECH FIG 3A,B). The cruciate ligaments are carefully examined: if there is any evidence of tumor invasion into the joint space, the femoral condyles are later resected en bloc with the proximal tibia.

The patellar tendon is sectioned 1 to 2 cm proximal to the tibial tubercle, and the entire capsule of the knee is detached circumferentially by electrocautery 1 to 2 cm from the tibial insertion.

The posterior capsule is carefully dissected under direct vision after the popliteal vessels have been mobilized by ligation of the inferior geniculate vessels. The cruciate ligaments are then sectioned close to the femoral attachments. To release the specimen, the tibia is osteomized 3 to 5 cm distal to the lesion, as determined by CT and MR imaging (TECH FIG 3C–E). The intermuscular septum is released under direct vision. An intra-articular resection of the knee joint is then completed.

**EXPOSURE OF THE KNEE JOINT AND REMOVAL OF THE PROXIMAL TIBIA**
Design features of currently used proximal tibia endoprostheses include modular components with an anterior metal loop for the attachment of the patellar tendon, porous coating for soft tissue incorporation, side holes for securing adjacent muscles, and a rotating-hinge knee mechanism (TECH FIG 4).

Uncemented prostheses are preferentially used for reconstruction after resection of a primary bone sarcoma in an adolescent or a young adult, whereas cemented prostheses are used for reconstruction after resection of metastatic tumors.

TECH FIG 4 • Current design features of proximal tibia endoprostheses include modular components with an anterior metal loop for the attachment of the patellar tendon, porous coating for soft tissue incorporation, side holes for securing adjacent muscles, and a rotating-hinge knee mechanism (Howmedica, Mahwah, NJ).
RECONSTRUCTION OF THE EXTENSOR MECHANISM AND MEDIAL GASTROCNEMIUS FLAP

- The remaining patellar tendon stump is advanced distally and secured tightly to the prosthesis with a 3-mm Dacron tape (Deknatel, Falls River, MA), which provides immediate mechanical fixation.
- An autologous bone graft, taken from the cut femoral condyles, is wedged and packed tightly between the porous-coated segment of the prosthesis and the tendon, facing both surfaces (TECH FIG 5). This will create a new bone–tendon junction.
- The soleus muscle is pulled anteriorly to cover the middle segment of the prosthesis and the medial gastrocnemius is used to cover its proximal segment (TECH FIG 6). The medial gastrocnemius muscle is detached at its muscle–tendon junction and interface with the lateral gastrocnemius, mobilized, and rotated anteriorly to cover the prosthesis. At its upper pole, the muscle flap is sutured to the patellar tendon to reinforce the prosthesis and bone graft reconstruction.
- Suction drains are positioned along the muscle envelope, and the fasciocutaneous flaps are pulled and closed, usually leaving a gap over the medial gastrocnemius flap, which necessitates coverage with a split-thickness skin graft taken from the ipsilateral thigh (TECH FIG 7).

TECH FIG 5 * A. Illustration showing reconstruction of the extensor mechanism, which has three components: attachment of the patellar tendon to the prosthesis, reinforcement of the attachment site with bone graft, and overlying medial gastrocnemius flap. B. Intraoperative photograph showing the patellar tendon sutured to the prosthesis and underlying bone graft. C–F. Alternatively, a circumferential polyethylene terephthalate (Trevira) tube may be applied on the prosthesis to which the patellar tendon and surrounding muscles can be sutured.² (A: Courtesy of Martin M. Malawer.)
TECH FIG 6 • Soft tissue coverage around the prosthesis. (A: Reprinted with permission from Clin Orthop Relat Res 1989;239:231–248; B,C: Courtesy of Martin M. Malawer.) (continued)
**TECH FIG 6 • (continued)**

D. The soleus muscle is pulled anteriorly to cover the middle segment of the prosthesis, and the medial gastrocnemius is transposed to cover its proximal segment. The medial sural artery to the medial gastrocnemius muscle is carefully preserved. E. The medial gastrocnemius muscle is detached at its muscle–tendon junction and interfaced with the lateral gastrocnemius, mobilized, and rotated anteriorly to cover the prosthesis. F. It is sutured to the border of the anterior muscles and the patellar tendon, forming a complete soft tissue envelope around the prosthesis.

**TECH FIG 7 • A–D.** Suction drains are positioned along the muscle envelope, and the fasciocutaneous flaps are pulled and closed, usually leaving a gap over the medial gastrocnemius flap that necessitates coverage with a split-thickness skin graft taken from the ipsilateral thigh. E,F. AP and lateral plain radiographs showing a proximal tibia endoprosthetic reconstruction. (A: Reprinted with permission from Clin Orthop Relat Res 1989;239:231–248.)
POSTOPERATIVE CARE

- The extremity is kept elevated and in full extension to avoid tension on the reconstructed patellar tendon for 5 days. Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.
- If there is no evidence of significant swelling by the end of the fifth day, the patient is allowed to walk with weight bearing as tolerated for 10 to 15 minutes at a time. If the extremity remains free of swelling, a gradual increment in exercise is allowed. The knee is kept fully extended in a knee immobilizer for 6 weeks, by the end of which gradual passive and active flexion of the knee joint are allowed.

OUTCOMES

- Proximal tibia resections are associated with considerably higher rates of flap ischemia, deep infection, and prosthetic loosening than limb-sparing resections at other sites, such as the proximal humerus and the proximal and distal aspects of the femur.
- The lower survival figures for prosthetic replacements at the proximal tibia (about 80% at 10 years compared to 95% for the others) are most likely attributable to the complexity of the surgical procedure and the soft tissue reconstruction, breakage of the polyethylene component, and mechanical failure. Impairment of the extensor mechanism is still the most prominent functional compromise after this resection.

- The incidence of infection has been dramatically decreased by the use of a gastrocnemius muscle flap. Strict adherence to postoperative management guidelines has also decreased the incidence of limb edema, wound problems, and magnitude of extensor mechanism dysfunction.

COMPLICATIONS

- Limb edema
- Flap ischemia to full-thickness necrosis
- Deep periprosthetic infection
- Dysfunctional extensor mechanism and extension lag
- Prosthetic loosening

REFERENCES

BACKGROUND

- The fibula is a rare anatomic location for both primary and metastatic bone tumors. When tumor does occur, it most commonly involves the proximal fibula, followed by the fibular diaphysis and the distal fibula.
- Primary bone sarcomas of the fibula have traditionally been treated with above-knee amputations. Increased use of limb-sparing procedures stimulated an interest in the surgical anatomy in this area and the possibility that tumors of the fibula might be safely resected.

ANATOMY

Proximal Fibula

- The proximal fibula is the attachment site for the lateral collateral ligament (LCL) and biceps femoris tendon and therefore has a role in determining lateral knee joint stability.
- The peroneal nerve turns around the base of the fibular head to enter the peroneus longus tunnel (FIG 1).

Fibular Diaphysis

- The fibular diaphysis is circumferentially surrounded by muscle origins at all aspects and anatomic levels.

Distal Fibula

- The distal fibular is a subcutaneous structure with minimal soft tissue coverage.
- It is the attachment site for the tibiofibular and calcaneofibular ligaments and therefore has a role in determining lateral ankle joint stability.

INDICATIONS

- Benign-aggressive tumors
- Primary sarcomas of bone
- Metastatic lesions of the fibula are usually treated with radiation therapy and rarely require surgery. This is because the fibula is not a major weight-bearing structure and bone destruction at that site does not compromise the mechanical stability of the lower extremity.
- Above-knee amputation is considered when a malignant tumor grossly invades the tibia or there is extensive multi-compartmental involvement, especially the posterior deep compartment.

IMAGING AND OTHER STAGING STUDIES

- In staging fibular tumors, emphasis is placed on the extent of bone destruction, intramedullary involvement, and soft tissue extension. Special attention is also given to the relation of the tumor to the peroneal nerve, blood vessels, and tibia.
- Plain radiographs and computed tomography are required to assess the extent of bone involvement and cortical destruction. These data are completed by magnetic resonance imaging (MRI), which shows the extent of medullary and extraosseous extension (FIG 2).

FIG 1 • A. The lateral collateral ligament and biceps femoris tendon attach to the fibular head and the peroneal nerve turns around the base of the fibula to enter the peroneus longus tunnel. B. Intraoperative photograph showing the peroneal nerve (N) as it enters the peroneus longus tunnel (open arrow). This tunnel has been opened to show the course of the nerve around the base of the fibular head. The biceps tendon (Bi) inserts on the fibular head away from the peroneal nerve. Vessel loops on the peroneal nerve are used to provide gentle traction for the dissection of the nerve branches.
SURGICAL MANAGEMENT

Positioning

- A semisupine position (45-degree elevation of the operated side) is used to permit easy access to the anterior and lateral compartments and allow dissection of the popliteal space. The entire extremity, from the inguinal ligament to the foot, is included in the sterile field to allow evaluation of the distal foot pulses and execution of an above-knee amputation, if indicated.
- The utilitarian fibular incision, which allows exposure and resection of tumors at all levels of the fibula, extends from the biceps above the knee joint, over the midportion of the fibula, anteriorly to the crest of the tibia, and then curves posteriorly and distally to the ankle. This permits the development of large anterior and posterior fasciocutaneous flaps.
- The anterior compartment, the lateral compartment (peroneal musculature), and the superficial posterior compartment consisting of the lateral gastrocnemius and soleus muscle are exposed, and the popliteal space and trifurcation can be explored through this incision. The biopsy site is removed en bloc with the tumor mass (FIG 3).

FIG 2 • A. Computed axial tomography of the proximal fibula shows an intermediate-grade fibrosarcoma with cortical breakthrough and extraosseous extension. B,C. Coronal and axial magnetic resonance images of the proximal fibula, respectively, showing a high-grade osteosarcoma with cortical breakthrough and extension to the anterior and lateral compartments of the leg. (Courtesy of Martin M. Malawer.)

FIG 3 • A. The utilitarian fibular incision extends from the biceps above the knee joint, over the midportion of the fibula, and anteriorly to the crest of the tibia, and then curves posteriorly and distally to the ankle. A component of the incision is used according to the level of resection: the proximal third is used for resection of the proximal fibula (B) and the proximal two thirds are used for intercalary resection (C). (A: Reprinted with permission from Clin Orthop Relat Res 1984;186:172–181.)
Three types of tumor resections are practiced around the proximal fibula: curettage and type I and II resections of the proximal fibula. Tumor curettage is done in benign-aggressive tumors and low-grade sarcomas associated with minimal cortical destruction and extraosseous extension (TECH FIG 1A). The types of proximal fibular resections have been previously described by Malawer. Type I resection includes the proximal fibula, a thin muscle cuff in all dimensions, and the LCL attachment site. The peroneal nerve and its motor branches are preserved and the tibiofibular joint is excised intra-articularly (TECH FIG 1B–D,H). This resection type is used for the management of benign-aggressive tumors and low-grade sarcomas that have caused considerable cortical destruction of the proximal fibula.

Type II resection includes an en bloc removal of the proximal fibula and the tibiofibular joint, the anterior and lateral muscle compartments, the peroneal nerve, and the anterior tibial artery (TECH FIG 1E–H). It is used for the management of high-grade sarcomas, which usually have considerable cortical destruction with extraosseous extension.

All type II resections necessitate anterior tibial artery ligation: in contrast, type I resections usually allow...
TECHNIQUES

Chapter 27  FIBULAR RESECTIONS 1967

TECH FIG 1 • (continued) G. This type of high-grade sarcoma of bone is managed with a type II resection, which includes an en bloc removal of the proximal fibula and the tibiofibular joint, the anterior and lateral muscle compartments, the peroneal nerve, and the anterior tibial artery. H. Cross-sectional anatomy of the proximal leg showing type I and type II resections. (H: Courtesy of Martin M. Malawer.)

preservation of that artery. A type II resection may also require sacrifice of the peroneal artery. Table 1 summarizes the anatomic structures removed en bloc with the various resection types of the proximal fibula.

Exposure

Curettage

- The common peroneal nerve is identified around the inferior border of the biceps femoris. If the nerve is to be preserved, as in tumor curettage or type I resection, its course under the peroneus longus is identified, the peroneus longus tunnel is unroofed, and the nerve is mobilized posteriorly away from the proximal fibula and marked with a vessel loop (TECH FIG 2).
- A longitudinal cortical window with oval edges is made above the lesion.

Type I and II Resections

- Large tumors of the proximal fibula may reach the midline posteriorly and push and distort the popliteal vessels. The major vessels are exposed by reflecting the lateral gastrocnemius muscle through its length and, if necessary, releasing the proximal tendinous origin from the lateral femoral condyle. This exposes the underlying soleus muscle, which is similarly detached through its substance near its fibular origin.
- The neurovascular bundle can be easily identified at the level of the popliteus muscle: the anterior tibial artery is positioned 2 to 3 cm distal to its inferior border. The peroneal artery lies close to the posterior aspect of the tibia and along the flexor hallucis longus muscle.
- The posterior tibial nerve is closest to the surface and the popliteal veins course between the nerve and the posterior tibial artery, which can be identified in the midline. The interval between the posterior fibular head and the posterior tibial and popliteal arteries must be explored

Table 1: Anatomic Structures Removed with the Various Resection Types of the Proximal Fibula

TECH FIG 2 • The common peroneal nerve is identified around the inferior border of the biceps femoris. The peroneus longus tunnel is unroofed to expose the nerve coursing around the fibular diaphysis.
and evaluated early to determine whether a high-grade sarcoma is resectable or a vascular graft will be required.

- The anterior tibial artery passes directly anteriorly through the interosseous septum, tying down the vascular complex and preventing mobilization. Applying traction on the popliteal artery, a simple maneuver, permits visualization of the anterior tibial artery origin. The anterior tibial artery and the two accompanying veins may then be ligated and transected, allowing the popliteal and posterior tibial arteries to fall away from the posterior surface of the mass. Completion of the vascular dissection proceeds distally.

**Tumor Removal**

**Curettage**

- Gross tumor is removed with hand curettes (TECH FIG 3A,B). Curettage should be meticulous and should leave only microscopic disease in the tumor cavity. Curettage is followed by high-speed burr drilling of the walls of the tumor cavity (TECH FIG 3C,D).

**Type I Resection**

- The LCL and biceps tendon are released at their fibular insertion. Muscle origin is transected by electrocauterization from the proximal shaft of the fibula. The anterior tibiofibular capsule can then be identified: its posterior aspect lies under the popliteus muscle.
- The capsule is incised and the joint opened, after which an intra-articular resection of the proximal fibula is carried out by performing an osteotomy 1 cm below the lower edge of the lesion (TECH FIG 3E).

**Type II Resection**

- The anterior and lateral musculature and the overlying deep fascia are excised. The origin of the anterior muscles from the shaft of the tibia is transected by electrocauterization. The distal level of the transaction is at the musculotendinous junction. The lateral collateral ligament, biceps tendon, and peroneal nerve are released 2.5 cm proximal to their fibular insertion. The anterior tibiofibular capsule can then be identified.
- A semicircular cut is made directly through the popliteus muscle toward the posterior aspect of the lateral tibial condyle. A fibular osteotomy is done 2 to 3 cm below the lower edge of the tumor (TECH FIG 3F). It is important to inspect the condyle after osteotomy and removal of the specimen. If the knee joint capsule had been exposed and opened, it should be repaired to prevent a synovial fistula.

**TECH FIG 3** • A. Macrosopic tumor is removed with hand curettes. B. Curettage of low-grade chondrosarcoma of the proximal fibula. C,D. Curettage is followed with high-speed burr drilling of the walls of the tumor cavity. (continued)
Chapter 27  FIBULAR RESECTIONS

Chapter 27  FIBULAR RESECTIONS

TECH FIG 3 • (continued) E. Type I resection of the proximal fibula. The tibiofibular joint is opened, the peroneal longus tunnel is unroofed to expose the peroneal nerve, muscle origins are transected from the proximal shaft of the fibula, and an osteotomy is performed 1 cm below the lower edge of the lesion. F. Type II fibular resection. The resection of the proximal fibula begins with exploration of the popliteal trifurcation posteriorly. The anterior tibial artery and often the peroneal vessels are ligated if there is a large posterior component to the tumor. A resection then proceeds, with release of all of the muscles attaching to the fibula posteriorly and preservation of the tibial nerve. The peroneal nerve is ligated before it enters the peroneus longus muscles. All of the tibialis muscles are released from the tibial border and are retained on the specimen side. The final step is an extra-articular disarticulation of the tibiofibular joint with a curved osteotome or a high-speed burr drill, removing a portion of the lateral tibial plateau with the joint en bloc. Care must be taken to avoid entering the knee joint. (F: Reprinted with permission from Clin Orthop Relat Res 1984;186:172–181.)

Reconstruction and Wound Closure

Curettage

- The tumor cavity is filled with bone graft or a bone substitute for benign-aggressive lesions in a young patient. Cement is used for reconstruction in adults, especially in low-grade sarcomas or metastatic lesions.

Type I and II Resections

- The LCL stump is attached to the lateral tibial metaphysis using a staple with the knee in 20 degrees of flexion after an osteoperiosteal flap has been formed (TECH FIG 4A–D). Fixation is reinforced with nonabsorbable sutures to the overlying iliotibial band and fascia.

- When the surgical field extends to the lower leg, the authors pull up the peronei and extensor digitorum longus tendons, thereby advancing the foot to a neutral position (to reduce the magnitude of foot drop and possibly avoid the need for an ankle-foot orthosis), and then tenodese the tendons to the tibial shaft using a 3-mm Dacron tape (TECH FIG 4E,F).

- The surgical defect is closed by rotating the lateral gastrocnemius muscle anteriorly to the deep fascia, covering the exposed tibia. The gastrocnemius muscle is sutured to the deep fascia and to the soleus muscle distally, as well as along the lateral capsule of the knee joint. The biceps tendon is then tenodesed to the gastrocnemius muscle (TECH FIG 4G).

TECH FIG 4 • A–D. The stump of the lateral collateral ligament is attached to the lateral tibial metaphysis using a staple with the knee in 20 degrees of flexion after an osteoperiosteal flap has been raised. (continued)
Tumors of the fibular diaphysis, whether benign or malignant, are usually treated with intercalary resection of the affected diaphyseal segment. Tumor curettage is neither feasible nor effective due to the small diameter of the diaphysis. Furthermore, loss of an intercalary segment usually does not affect the stability of knee and ankle joints or the overall function of the lower extremity. Benign tumors require resection of bone only, while high-grade sarcomas require en bloc removal of the surrounding cuff of muscles.

**Exposure**
- Intercalary fibular resections are performed using the middle portion of the utilitarian incision with proximal...
or distal extension, according to anatomic extent of the affected segment.

- To expose the fibular diaphysis, the fascia is opened in line with the utilitarian incision. The plane between the peronei and the soleus is defined by the septum separating the two compartments. The soleus is detached from its fibular origin and, along with the lateral gastrocnemius muscle, is retracted medially and proximally to reveal the posterior crest of the fibula (TECH FIG 5).

- The flexor hallucis longus can be spared or resected, depending on the grade and local extent of the underlying tumor. The peronei are mobilized anteriorly, and retractors are positioned underneath the fibula.

**Tumor Removal**

- Resection is performed at the level that had been determined before surgery. Care must be taken not to damage the peroneal vessels, which are posterior and parallel to the fibula.

---

**TECH FIG 5**  
**A.** Plain radiograph showing fibrous dysplasia of the fibular diaphysis.  
**B.** Operative photograph showing exposure of a benign-aggressive tumor. The soleus (So) is detached from its fibular origin and, along with the lateral gastrocnemius muscle (G), is retracted medially and proximally to reveal the posterior crest of the fibula (arrow). The flexor hallucis longus can be spared or resected, depending on the grade and local extent of the tumor. The peronei muscles (Pe) are mobilized anteriorly, retractors are positioned underneath the fibula, and the resection is performed at the level determined before surgery.  
**C.** Postoperative radiograph.  
**D.** Plain radiographs showing Ewing sarcoma of the fibular diaphysis. (B: Courtesy of Martin M. Malawer.) (continued)
TECH FIG 5 • (continued) E. The tumor is exposed using the upper two thirds of the utilitarian fibular incision. F. Because of the extraosseous tumor extension, the soleus is split to expose and mobilize the neurovascular bundle; the muscle remains attached to the fibula.

Reconstruction and Wound Closure

- Intercalary resections usually do not require osseous reconstruction. Low intercalary resections that leave only a short segment may require reinforcement of the lateral malleolus to preserve lateral ankle stability (TECH FIG 6).
- Distal resections of the fibula, which are rarely done, require reconstruction because of the loss of a component of the ankle joint. Reconstruction with a microvascularized fibula is recommended.
- Alternatively, the ipsilateral fibula can be used for reconstruction. A type I resection of the proximal fibula is performed, and the fibular head and neck are attached to the tibial plafond with a screw and to the fibular shaft with a plate (TECH FIG 6C).

TECH FIG 6 • A,B. Plain radiographs showing reinforcement of the lateral malleolus by means of a screw after low intercalary resection of the fibula. C. A distal fibular defect can be reconstructed with a microvascularized fibula from the contralateral leg or transposition of the ipsilateral proximal fibula.
PEARLS AND PITFALLS

**Proximal fibula resection**

- **Intraoperative**
  - Semisupine position with flexed knee using the utilitarian fibular incision
  - Mobilization and protection of the peroneal nerve
  - Exploration of the popliteal vessels, when required
  - Selection of surgery (curettage/type I or II resection) according to tumor type and anatomic extent
  - Reconstruction of the LCL attachment site after resection of the proximal fibula

- **Postoperative**
  - Specific rehabilitation according to the tumor type, including ankle–foot orthosis for patients who underwent type II resection

- **Fibular diaphysis resection**
  - A utilitarian incision of adequate length for wide exposure of the resected fibular segment
  - En bloc resection of the surrounding cuff of muscles in high-grade sarcomas
  - Mandatory reinforcement of the lateral malleolus in low intercalary resections

**POSTOPERATIVE CARE AND REHABILITATION**

**Proximal Fibula Resection**

- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.

**Curettage**

- Early ambulation is encouraged with partial weight-bearing for 3 weeks as well as passive and active range of motion of the knee joint. Unrestricted weight bearing is allowed upon wound healing.

**Type I and II Resections**

- Postoperatively, the extremity is immobilized in a cast for 3 weeks in 20 degrees of knee flexion to allow soft tissue healing. After cast removal, full weight bearing is allowed as well as full active range of motion around the knee.
- An ankle–foot orthosis is required for patients who underwent type II resection and had foot drop because of peroneal nerve dysfunction.
- Patients who have high-grade sarcoma are treated with postoperative chemotherapy.
- Patients with Ewing sarcoma are further treated with radiation therapy consisting of external beam radiation of 6,000 to 7,000 Gy.

**Fibular Diaphysis Resection**

- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed.
- This is followed by early ambulation with partial weight bearing for 3 weeks, together with passive and active range of motion of the knee joint. Unrestricted weight bearing is allowed after wound healing.

**OUTCOMES**

- Resections of the fibula, even those that require en bloc resection of the muscle cuff, are usually associated with minimal impact on lower extremity function.

- The weight-bearing capacity of the leg is not impaired and its major muscle groups usually remain intact. The only exception is the occurrence of foot drop and the need to use an ankle–foot orthosis after intentional resection of the peroneal nerve in a type II proximal fibular resection.
- Knee stability is similarly preserved when care is taken to adequately reconstruct the LCL attachment site and allow its healing and gradual loading.

**COMPLICATIONS**

- Peroneal nerve injury in curettage or type I resection of the proximal fibula
- Lateral knee instability due to inadequate LCL reconstruction or inadequate postoperative rehabilitation
- Lateral ankle instability because of inadequate fixation of the lateral malleolus in low intercalary resections of the fibular diaphysis
- Chronic swelling of the leg after extensive type II resection, requiring lymphatic drainage
- Deep infections

**REFERENCES**

BACKGROUND

- Wide resection of long-bone tumors can create a large intercalary bone defect requiring reconstruction. Such defects were traditionally reconstructed with prosthetic implants, allografts, and allograft–prosthetic composites, all of which were associated with considerably high rates of complications and failure.
- Distraction osteogenesis provides biologic reconstruction of only small to medium intercalary defects. Moreover, it is a prolonged procedure, requiring up to 2 months for an elongation of 1 cm, complications are frequent, patient compliance is critical, and large soft tissue defects cannot be addressed simultaneously.
- Reported experience regarding safety and efficacy in the oncologic setting is also limited.

Since the introduction of vascularized autogenous graft for long-bone reconstruction after tumor resection in the early 1970s, the use of a free fibular flap has become a viable option for reconstructing large intercalary bone defects after tumor resection or for resection-arthrodesis. Its inherent advantage is based on its ability to exploit the biology of normal fracture healing rather than the creeping substitution that is fundamental to the incorporation of a nonvascularized graft.

- The fibula is an optimal vascularized graft source because of its anatomic accessibility and because removing an intercalary segment while preserving the proximal fibula and lateral malleolus would have minimal impact on knee and ankle stability and would not compromise the weight-bearing capacity and overall function of the lower extremity. It allows reconstruction of large bone defects because of its independent blood supply, which permits graft incorporation into the host bone even when the presence or viability of the surrounding soft tissue is considerably compromised because of previous surgery or radiation therapy.
- The fibular head can also be used for joint reconstruction after intracalary resection of bone tumors. Furthermore, a vascularized fibular graft has the ability to hypertrophy over time in response to continuous pressure load. As a result, vascularized fibula have shown excellent long-term durability.
- In summary, a free fibular graft provides a durable true biologic reconstruction with accommodative and regeneration capabilities and has minimal short- and long-term complications. It requires a combined effort of highly trained and committed teams as well as the patient’s compliance throughout a very long, complex, and demanding rehabilitation period.

ANATOMY

- The fibula is long and narrow and therefore provides a strong cortical strut for reconstruction of long-bone defects. It has a square cross-section in its superior part and is triangular in its inferior end. In the adult, it can reach a width of 1.5 to 2 cm and a length of 35 cm, 25 to 30 cm of which can be harvested for free grafting. Its shape and length can match bone segments of the upper extremity (humerus, radius, and ulna) or can fit the medullary canal of bones of the lower extremity (femur, tibia); it therefore can be used to reconstruct bone defects at these sites.
- The fibula is circumferentially surrounded by muscle groups on its lateral, anteromedial, and posterior aspects and is also the origin of the four intermuscular septa of the leg. The blood supply and drainage of the fibular shaft are related to the peroneal vessels. The peroneal artery, together with the two peroneal venae comitante, follow a course parallel to the fibula and lie between the flexor hallucis longus and tibialis posterior muscles. The fibula is dually vascularized through its endosteal and periosteal vessels.
- The endosteal blood supply is based on the nutrient artery, which stems 6 to 14 cm from the peroneal artery bifurcation, enters the middle third of the diaphysis via the nutrient foramen, and then divides into an ascending and a descending branch. The periosteal blood supply is derived from eight to nine periosteal branches, mostly in the middle third of the diaphysis. The peroneal artery is also the source of four to six fascial vessels that pass through the posterior intercrural septum to the skin territory, lateral to the fibula. It provides numerous muscular branches as well: specifically, it supplies multiple small branches to the muscles of the anterior compartment and a few larger branches to the soleus muscle at the deep posterior compartment of the leg.
- The unique morphologic characteristics and blood supply of the fibula allow considerable versatility in the use of the fibular flap for reconstruction of skeletal, soft tissue, and growth plate defects. The fibular flap can be transferred in various configurations and compositions to suit the needs of individual cases:
  - In its straight configuration, it can be used to reconstruct a relatively narrow bone segment. A longitudinal osteotomy that increases the surface area of the flap can serve as an onlay graft to augment the healing process for partial cortical defects. Based on perforating fasciocutaneous branches at the middle and distal thirds of the pedicle, a skin paddle of up to 20 × 10 cm can be transferred simultaneously to facilitate coverage of concomitant large soft tissue defects and to allow the patency of the pedicle anastomosis to be monitored. Part of the soleus or the flexor hallucis longus muscles can also be included with the flap to reconstruct soft tissue defects and cover exposed bone.
H

A. The blood supply and drainage of the fibula are related to the peroneal artery and two peroneal veins, which follow a course parallel to the fibula. The fibula has a dual blood supply: endosteal and periosteal. The former is based on a nutrient artery that stems 6 to 14 cm from the peroneal bifurcation; the latter is based on multiple periosteal branches along the fibular diaphysis. B. Diaphyseal fibular graft used to reconstruct intercalary bone defects. If a long segment is required and the osteotomy is close to the lateral malleolus, screw fixation to the tibia is advised to prevent valgus deformity and ankle instability. C-G. A skin paddle can be transferred simultaneously to facilitate coverage of concomitant large soft tissue defects and to allow patency of the pedicle anastomosis to be monitored. H. A proximal fibular graft that includes the proximal fibular epiphysis and is based on the anterior tibial vascular pedicle may be used for joint reconstruction and preservation of longitudinal growth in children after intra-articular resection of bone tumors.
Transverse osteotomies can be made through the mid-diaphysis to produce two or more cortical struts on a single pedicle (double or triple barrel) to reconstruct a wide bone segment. When the periosteal vessels are transected, the bone survives on its endosteal system.

The proximal epiphysis may be included in the flap for joint reconstruction and preservation of longitudinal growth potential (in pediatric patients) after intra-articular resection of bone tumors (FIG 1H). This flap is based on the anterior tibial vascular flap or the descending geniculate artery and is most commonly used for reconstructions after resections of the proximal humerus and distal radius.

**INDICATIONS**

- Segmental bone defects larger than 5 cm after resection due to tumor, radiation-induced bone necrosis, or osteomyelitis
- In high-grade sarcomas of bone, we generally use spacers for immediate reconstruction after tumor resection rather than performing the definitive reconstruction with vascularized fibula. The latter is carried out 2 years after tumor resection if there has been no tumor recurrence or lung metastases.

**CONTRAINDICATIONS**

**Systemic and General Conditions**

- Cardiovascular, surgical, or hematologic diseases that may affect peripheral blood flow
- Poor compliance, or if the patient’s physical or psychological state would not allow a prolonged non-weight-bearing period and rehabilitation
- Poor general health

**Donor Site Considerations**

- Fibular deformity after previous injury to the lower extremity
- Vascular injury or compromise after previous trauma to the leg
- Vascular anomalies of the leg or plantar arches (eg, single-vessel foot)

**Recipient Site Considerations**

- Infection around the recipient site
- Suspected tumor recurrence

**IMAGING AND OTHER STAGING STUDIES**

Detailed preoperative evaluation of both the recipient and donor sites is mandatory. Imaging of the recipient site should provide information about the dimensions of bone (length and diameter) and soft tissue defects remaining after tumor resection, thus allowing the selection of the appropriate type and size of fibular flap to be used. Imaging of the donor site should include the entire leg and is aimed at excluding fibular deformity and determining maximal flap length. The surgeon should verify adequate pulses in both posterior tibial and dorsalis pedis arteries.

- The deep and superficial plantar vascular arches are evaluated using an equivalent to the palmar Allen’s test, confirmed by Doppler ultrasound examination. If those studies are inconclusive, angiography or magnetic resonance angiography is performed.

**Recipient Site**

- Plain radiography
- Computed tomography (CT)
- Magnetic resonance imaging (MRI)

**Donor Site**

- Plain radiography
- Magnetic resonance angiography
- Angiography
- Doppler ultrasound

**SURGICAL MANAGEMENT**

**Positioning**

- For treating a bone defect of the lower extremity, the patient is placed supine on the operating table with the thighs spread. The hip and knee of the donor extremity are flexed (FIG 2). The first team, which is responsible for tumor resection (blue team), is positioned along the medial or lateral side of the recipient extremity. If tumor resection is done from the medial side of the extremity, a surgeon can be positioned at that aspect. A second (red) team, responsible for the harvest of the fibular flap from the donor extremity, is positioned along its lateral aspect (Fig 2).
To minimize the duration of surgery, if the patient’s position on the operating table permits, the fibular flap is harvested as the recipient site is being prepared, a procedure that may include resection of the primary bone tumor or removal of a spacer that had been used in a previous surgery for reconstructive purposes.

INTERCALARY RESECTIONS

- As a rule, a vascularized fibula in its straight and simple configuration is sufficient for reconstructing bone defects of the upper extremity because of the relatively narrow cross-sectional diameter of the latter. Reconstruction of such defects of the lower extremity requires graft material of a larger diameter because of the additional mechanical support needed. A double-barrel fibular flap can be used to reconstruct femoral and tibial defects of up to 13 cm.
- Longer defects may require the support of an allograft, which provides the initial stability required for bone healing, graft incorporation, and subsequent fibular hypertrophy. Furthermore, in cases of failed vascular anastomosis, the combined fibular–allograft construct is still comparable to multiple cortical allogenic struts with a relatively good chance of success, especially if reliable fixation is achieved.
- The technique of combined reconstruction with an allograft and the vascularized fibula, as described by Capanna and colleagues, provides such stability and is the preferred method of reconstruction that we use for long intercalary defects of the lower extremities.1,2

RESECTION OF BONE TUMOR

- The bone tumor is removed according to the standard techniques, and the length and diameter of the intercalary bone defect are measured (TECH FIG 1).

TECH FIG 1 • A. Diaphyseal tumor is resected with wide margins, leaving a long intercalary bone defect. B. Plain radiograph of the tibia showing a large diaphyseal low-grade osteosarcoma. C. Intraoperative photograph of the tumor. D. Large intercalary defect remaining after wide tumor resection. E. Plain radiograph of the arm showing considerable bone loss and pathologic fracture associated with acute osteomyelitis of the humeral diaphysis. F. After tissue sampling and cultures, administration of intravenous antibiotics, and resolution of acute manifestations of infection, the patient underwent resection of the infected bone tissue, leaving a long intercalary bone defect.
HARVEST OF A FIBULAR FLAP

- Using an anterolateral incision at the contralateral leg, an intercalary fibular segment that is 6 cm longer than the bone defect is harvested, together with its nutrient vessels and its periosteal cuff (TECH FIG 2A,B). If a large skin defect is anticipated at the tumor resection site, the fibular flap is harvested with an overlying skin island supplied by the same peroneal artery, which allows tension-free skin closure as well as early detection of compromised viability of the flap: arterial or venous compromise would instantly be expressed by ischemic or congestive changes of the skin island (TECH FIG 2C).

- If a long bony segment is required and the osteotomy is close to the lateral malleolus, screw fixation to the tibia is advised to prevent valgus deformity and ankle instability (see Fig 1B). A skin graft, usually taken from the thigh of the donor extremity, is used to cover the skin defect in that leg. The peroneal tendons should be well covered by muscle bulk to enable a safe skin graft take.

PREPARATION OF THE ALLOGRAFT

- The allograft is cut to the same length as the bone defect and a groove is opened longitudinally by removing as much cortical and cancellous bone as needed to allow insertion of the fibular flap into it.

RECONSTRUCTION OF THE RECIPIENT SITE

- The allograft is inserted to fill the bone defect and is fixed to its proximal and distal edges with a side plate and screws (TECH FIG 3A,B). An intramedullary nail is also used if the allograft medullary canal is wide enough to contain both the nail and the fibular graft. Using a high-speed burr, a defect is created in the allograft cortex at the appropriate level to allow the passage of the fibular vascular pedicle toward the vascular bundle of the recipient extremity while avoiding traction on the vascular Anastomosis (Tech Fig 3A,B).

- The fibular graft is inserted 2 to 3 cm into the medullary canal at both ends and fixed with screws (TECH FIG 3C–E). Care is taken to prevent damage to the nutrient vessels of the fibula by those screws. The fibula can be placed in an intramedullary location, inside the allograft or parallel to it. In both options, the fibular osteotomy sites should lie close to the native long-bone resected edges.

- After vascular anastomoses are completed, autologous bone graft, taken from the fibular flap remnants or the ipsilateral iliac crest, is used to reinforce the interface between the fibula and the recipient bone.
Chapter 28  FREE VASCULARIZED FIBULAR GRAFTS FOR RECONSTRUCTION OF SEGMENTAL BONE DEFECTS 1979

**INTRA-ARTICULAR RESECTIONS**

- The proximal fibular epiphysis, with variable lengths of the diaphysis and with the anterior tibial vessels as the vascular pedicle, or alternatively the inferior geniculate artery, is used to reconstruct defects that include one side of the articular surface. After removal of the fibular flap the lateral collateral ligament is secured to the medial tibial metaphysis with a metal staple to preserve lateral knee joint stability (**TECH FIG 4A**).
- The proximal aspect of the fibular flap is fixed to the radial or humeral diaphysis with a side plate and screws, and the biceps tendon stump is used for attachment to the opposing articular surface soft tissue envelope (**TECH FIG 4B–E**).
POSTOPERATIVE CARE

- All patients must be treated and monitored postoperatively according to a strict and constant protocol. They are admitted to the intensive care unit for the first 5 days after surgery, where they are monitored for vital signs and flap viability. A high volume of lactated Ringer solution (1.5 times maintenance) is given to ensure high flow through the anastomosis and prevent thrombus formation. The high volume of fluids is maintained for a total of 3 days, with gradual reduction to normal maintenance volume in the ensuing 2 days.
- Enoxaparin is given to prevent deep vein thromboses. Blood samples are drawn twice daily for blood count and electrolytes. Hemoglobin levels are kept at 9 to 10 g/mL to minimize blood viscosity and further decrease the likelihood of anastomotic thrombus. A technetium methylene diphosphonate bone scan with single-photon emission computed tomography is performed 10 days after surgery to evaluate flap viability.
- Recipient extremities are immobilized for 3 months (upper extremity by a brace, lower extremity by a plaster cast), after which gradual passive range-of-motion exercises are practiced.
- Signs of bone union are evaluated radiologically by serial plain radiographs. Bone unions are usually seen after 4 to 5 months in the upper extremity and after 5 to 7 months in the lower extremity. Partial weight bearing is allowed upon detection of radiologic evidence of bone union. Gradual physical loads on the limb are recommended until full weight bearing is achieved.

OUTCOMES

- Solid bony unions, associated with fibular hypertrophy, full weight bearing, and mechanical load capacities, are achieved in the vast majority of patients. Fibular hypertrophy occurs over years and is the result of pressure transport, microfractures, and callus formation.
- Mild to moderate decreases in range of motion are common and are similar to those seen after other types of reconstructive surgeries. Such decreases result from the extent of resection of bone and soft tissues rather than the mode of reconstruction.
- Deep infections are rare, as is hardware failure requiring revision surgery.

COMPLICATIONS

Recipient Site

- Anastomotic thrombosis and loss of flap viability
- Nonunion
- Infection
- Hardware failure and breakage

Donor Site

- Valgus ankle deformity
- Ankle joint instability
■ Transient or permanent peroneal palsy
■ Transient or permanent peroneal distribution area sensory deficit
■ Skin graft failure and tendon exposure
■ Transient or permanent great toe flexion impairment

REFERENCES
BACKGROUND

- An intercalary reconstruction is defined as replacement of the diaphyseal portion of a long bone after segmental skeletal resection (diaphysectomy).
- Intercalary reconstructions typically result in superior function compared to other limb-sparing procedures because the patient’s own joints above and below the reconstruction are left undisturbed.
- Most intercalary reconstructions are performed with bulk allografts, although various endoprosthetic intercalary prostheses are available.
- Allograft reconstructions require osseous healing for long-term stability; initial allograft stability must be obtained with intramedullary nailing or internal fixation.
- Allografts have a long-term risk of fracture likely related to the size and type of fixation.
- Intercalary allografts are often supplemented with vascularized fibular grafts.
- Endoprosthetic reconstruction has typically been limited to small, central tumors as significant lengths of bone proximal and distal to the lesion are required for successful fixation of traditional prosthetic stems.
- New implant designs have expanded the indication for intercalary prostheses by drastically reducing the length of bone needed to achieve stable fixation.
- Segmental prostheses typically provide immediate stable fixation, allowing early rehabilitation and rapid return of function.
- Vascularized fibular grafts are not required for intercalary implants.
- Although aseptic loosening has been reported after endoprosthetic reconstruction, it is rarely if ever seen with intercalary implants; the lack of bearing surfaces contributing to wear debris formation and the lack of exposure to joint fluid help to protect the implant.

INDICATIONS

- Intercalary reconstructions are indicated for osseous joint-sparing reconstructions.
- Intercalary reconstructions are performed most commonly in the femur, tibia, humerus, and forearm.
- Intercalary reconstructions require adequate remaining bone stock to allow stable fixation; if inadequate bone remains, the procedure should be converted to a joint-replacing reconstruction.
- Intercalary allograft reconstructions require osseous healing for long-term stability, which can be compromised by chemotherapy or radiation during the healing period.
- Intercalary allografts in areas with poor vascularity, with small residual host segments, in heavy or very active patients, or with planned radiation or chemotherapy likely benefit from supplemental vascularized fibular allografts.
- Intercalary endoprosthetic reconstruction is an option if allograft reconstruction is contraindicated due to poor host factors or in patients with prior failed allograft reconstruction.
- Modular intercalary prostheses provide the flexibility to easily convert to a conventional endoprosthetic replacement either at initial surgery or for later revisions by using joint-replacing modules at either end of the implant.

ANATOMY

- Anatomic considerations in the femur include the anterior bow, femoral anteversion, and the proximity of the superficial femoral artery to the distal femur near the adductor hiatus.
- Anatomic considerations in the tibia include the limited soft tissue coverage anteromedially and the proximity of the posterior tibial neurovascular bundle to the posteromedial tibia.
- Anatomic considerations in the humerus include the proximity of the radial nerve to the posterior midhumeral shaft.
- Anatomic considerations in the forearm include the radial bow.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Table 1 outlines methods for examining the patient with a mass or suspected tumor.
- Important aspects of the patient history include:
  - Onset of mass or pain
  - Progression of growth or pain
  - Constitutional symptoms (fevers, chills, night sweats, weight loss)
  - Personal or family history of cancer

IMAGING AND OTHER STAGING STUDIES

- Radiographs are the primary imaging study used in forming a differential diagnosis of bone lesions.
- Radiographs are used to assess the geometry and size of the host bone and the lesion to allow appropriate sizing of the allograft reconstruction.
- Radiographs are helpful in determining the response to chemotherapy, which influences the decision making for limb salvage.
- Bone scan is used to determine if there are additional osseous sites of disease.
- Computed tomography (CT) scanning is used to determine the bone geometry and to assess bone destruction by a lytic lesion.
- Magnetic resonance imaging (MRI) is used to assess the soft tissue extension of a lesion. It is also used to assess the prox-
imity of neurologic and vascular structures, the intraosseous or narrow extent of tumor, and extension into an adjacent joint.

- Sagittal and coronal MRI images are extremely useful in planning the resection length; measurements from the adjacent joints to the planned levels of osteotomy are made to provide a reproducible method of identifying the levels intraoperatively.
- The role of positron emission tomography (PET) scanning has yet to be defined for sarcomas. It likely plays a role in the assessment of metastatic disease.

**SURGICAL MANAGEMENT**

- The main surgical decisions to be made when performing an intercalary resection are the type and length of fixation and the need for supplemental vascularized fibula graft.
- Plate fixation allows for reconstruction with standard osteosynthesis techniques.
- Plate fixation allows for compression across the allograft–host junctions, which likely improves healing.
- Plate fixation results in screw holes in the allograft, which is thought to contribute to late allograft fracture.
- Intramedullary fixation of allografts requires additional incisions but likely provides stronger fixation.
- Intramedullary fixation provides long-term protection of the allograft without placing screw holes in the allograft (FIG 1).
- Intramedullary fixation makes it difficult to obtain compression at the allograft–host junctions, which may impede healing.

- Allograft and host cuts can be transverse or stepped (FIG 2).
- Transverse cuts make rotational adjustments easier and likely result in less periosteal dissection, which may improve healing.
- Stepped cuts are more technically difficult, add surgical time, and may cause more damage to the local periosteum. However, they likely increase host–allograft bone contact, which may improve healing.
- Intercalary implants require careful attention to resection length and canal preparation to ensure optimal fixation of the implant stems.
- Regardless of the method of skeletal reconstruction, careful attention to the soft tissues and use of rotational muscle flaps when indicated are necessary to reduce the risk of wound complications and subsequent infection.

**Preoperative Planning**

- Preoperative planning is extraordinarily critical in these complex reconstructive procedures.
- Multiple imaging techniques should be used to fully assess the tumor, length of resection, and the remaining bone anatomy necessary to support the planned reconstruction.
- Standard instruments for tumor resection are required, including bone saws; equipment for additional procedures such as vascular bypass, vascularized graft, or specialized soft tissue reconstruction should be available.
- Some surgeons prefer to use a separate group of instruments for the resection and the reconstruction.

**FIG 1** Placement of intramedullary nail and compression of junction. **A.** Fluoroscopic view of intramedullary nail through allograft in the proximal femur. The K-wire for rotational reference can be seen. Gaps in the host–graft junction are present without compression of the junction. **B.** Fluoroscopic view after placement and tightening of compression screw in intramedullary nail. Gap at host–allograft junction is minimized.
The allograft needs to be ordered from a bone bank. Some surgeons prefer to size-match allografts used for intercalary reconstructions, requiring radiographs of the allograft to be obtained before ordering.

If a vascularized fibula graft is planned, the timing and host location of the graft must be determined.

Endoprosthetic implants may require customized components, typically requiring a 3- to 4-week lead time to allow for design and manufacturing of the implant.

An examination under anesthesia focusing on the rotational profile of the nonoperative leg can be useful in ensuring proper rotation of the operative leg.

Intraoperative C-arm fluoroscopy is useful to measure and select the levels of planned bone osteotomy.

**Positioning**

- Positioning depends on the tumor location and the surgical approach required for oncologic resection.
- Femoral resections are typically performed either in the supine or lateral position; tibial cases are performed supine.
- Femoral reconstructions may be facilitated by a bump under the buttock, but this may make clinical assessment of rotation more difficult.
- Forearm reconstructions are performed with the patient supine and the arm on a hand table.
- Humeral reconstructions can be performed with the patient in the supine or beach chair position.

**Approach**

- The approach for intercalary reconstructions is determined by the incision needed to perform an adequate resection of the tumor.
- Femoral reconstructions are ideally performed through a lateral or anterolateral approach to the thigh; medial incisions may be necessary to isolate and protect the superficial femoral artery and vein during the resection.
- Tibial reconstructions can be performed through an anterolateral or anteromedial approach.
- An anteromedial approach is more likely to require complicated soft tissue coverage.
- Humeral resections are performed through an extensile anteromedial approach; care must be taken to identify and protect the radial nerve when oncologically possible.
- Forearm reconstructions of the radius are ideally performed through an anterior approach.

**RESECTION**

- The approach is performed as indicated by the location of the tumor and the biopsy.
- Pertinent vascular and neurologic dissection is performed to identify and protect critical structures; soft tissue dissection around the tumor mass is then performed.
- Dissection is performed down to bone at the distal and proximal extent of the planned bone resection.
- Using fluoroscopy or other measurements from preoperative imaging, K-wires placed perpendicular to the shaft of the bone may be used to mark the proximal and distal osteotomy level. Care should be taken to avoid excessive damage to the periosteum adjacent to the planned osteotomy.
- Before osteotomy, the bone should be carefully examined and marked to ensure proper rotational orientation during the reconstruction. The linea aspera of the femur is a convenient anatomic landmark; K-wires or cuts in the bone may be placed proximal and distal to the resection area as well.
- Transverse osteotomy is performed with a power saw. Cooling the saw blade with irrigant prevents excessive heat from causing thermal damage to the host bone.
- The specimen is removed, the length is measured and recorded, and margins are assessed.

**PREPARATION OF THE ALLOGRAFT**

- The allograft is thawed in antibiotic-laden lactated Ringer solution.
- The section of the allograft that most closely matches the shape and size of the resected bone is marked. A few millimeters are added to the resected length to allow additional small cuts to be made to improve the bone contact and alignment with the host bone.
- The proximal and distal allograft cuts are made with a power saw.
- If intramedullary nail fixation is planned, the allograft is then reamed to a diameter 2 mm greater than the planned nail diameter.
- Reaming should be done slowly and progressively to avoid cracking the very brittle allograft.
INTRAMEDULLARY FIXATION (FEMUR)

Following Resection

- A small incision is made approximately 8 cm proximal and slightly posterior to the greater trochanter (TECH FIG 1).
- A guidewire is placed at the appropriate starting point for the type of nail being used, either the piriformis fossa or the tip of the greater trochanter.

Alternatively, if a retrograde nail is planned, a small medial arthrotomy is performed and the guidewire is inserted into the distal femur in the intercondylar notch.

After confirming the wire position with fluoroscopy, an entry reamer is used to open a portal into the proximal (or distal) femur.

TECH FIG 1 • A–D. Osteosarcoma of the femur in a 14-year-old boy reconstructed with an intercalary allograft with plate fixation. A. Preoperative AP radiograph showing diaphyseal lesion. B. Coronal MRI image showing intramedullary and extramedullary extent of the lesion. C. Postoperative AP radiograph showing intercalary reconstruction with medial and lateral locking plates. The most distal medial screw in the epiphysis was later removed to allow continued growth across the distal femoral physis. D. Postoperative lateral radiograph showing the reconstruction with callus formation at the host–allograft junctions. E–G. Customized modular femoral intercalary reconstruction in a patient with Ewing sarcoma. E. Sagittal MRI scan showing length of tumor to be resected. F. Resection specimen and implant; cross-pin fixation is used for improved stability of the short stems. G. Intraoperative view of intercalary implant; surfaces are porous for extraskeletal fixation at the prosthetic bone junctions. H,I. Radiographs of proximal and distal femur showing intercalary implant. (continued)
J–P. Salvage of multiply failed intercalary allograft with conversion to intercalary endoprosthesis. 

J. Chronic painful nonunion of distal allograft–host junction despite repeated surgery and vascularized fibular bone grafting. Patient had been braced for 5 years and unable to bear weight for over 2 years. 

K. Resection of allograft with failed blade plate; cultures of allograft showed infection with methicillin-sensitive Staphylococcus aureus. 

L. Use of high-dose antibiotic spacer for sterilization of soft tissues while preserving limb length and tissue pocket for planned reconstruction. 

M. Preparation of intramedullary canal using facing reamer and (N) use of jigs for anchor plug fixation with bicortical transfusion pins. 

O. Intraoperative view of assembled prosthesis; locking collar and screws are used to hold proximal and distal body segments together. 

P. Radiograph showing final reconstruction. The patient is completely pain-free and ambulatory without braces or crutches.

- A beaded guidewire is inserted into the femur, across the resection bed, and into the femoral segment on the far side of the resection bed. 
- The femur is then progressively reamed to 1.5 mm larger than the planned nail diameter. 
- The beaded guidewire is partially pulled out and the allograft is inserted into the resection bed. 
- The guidewire is then passed back through the allograft into the far femoral segment. 
- A preliminary check of the bone cuts is made by manually compressing the allograft against the host bone and inspecting bone contact and alignment. Small revision cuts may be required on the allograft. 
- The nail is then inserted. With the nail in place, a final inspection of the junctions is made and revision trimming of the allograft is performed to improve bone contact. 
- The nail is fully seated. 
- The locking screws in the “distal” tip of the nail are placed. These may be the screws in the proximal femur if a retrograde nail is being used. 
- The nail is then backtapped to close down any gaps in the host–allograft junctions.
Rotation is checked either clinically or by aligning the previously placed K-wires.

The screws in the “proximal” end of the nail are placed. If a compressible nail is being used, the compression screw is applied after placement of the dynamic locking screw (TECH FIG 2). Because of the extended time often required for healing, two locking screws should be placed proximally and distally.

If compression has been applied with a compression nail and the allograft is rotationally stable, no additional fixation is required.

If the allograft is rotationally unstable around the nail, a short plate can be applied with unicortical screws to improve stability. This can be placed at one or both host–allograft junctions depending on the amount of instability.

Plate and Screw Fixation

The allograft is placed into the resection bed and gross alignment is checked (TECH FIG 3).

If necessary, the plate is contoured to match the alignment of the femoral segment being reconstructed.

A 4.5-mm plate should be used (except in the forearm). The type of plate is dictated by the location. Special plates are available for the proximal and distal femur.

A slight prebend of the plate is performed to maximize compression of the junction on the side opposite the plate.

The plate is positioned and fixed to one side of the host bone with one screw.

The host–allograft segment is aligned and the plate is positioned appropriately (TECH FIG 4).

Rotational alignment is checked clinically or with the previously placed K-wires.

Compression is applied across the host–allograft segments either with a tensioning device or a Verbrugge clamp and a pull screw (TECH FIG 5).

Sagittal and coronal plane alignment is verified with fluoroscopy.

Allograft trimming is performed as necessary to improve bone contact and alignment.
Compression screws are placed into the plate to maximize compression across the host–allograft junctions.

Two screws are placed through the plate into the allograft to prevent dislodgement. If a locking plate is being used, these can be unicortical locking screws. Alternatively, cerclage cables can be placed to avoid holes in the allograft.

In resections resulting in very small residual host segments, large plate fixation may not be possible. In these cases, small hand or foot plates may be beneficial for fixation. Alternatively, oblique compression screws from the host through the allograft may be used.

**Closure**

- Irrigation of the wound is performed and hemostasis obtained.
- If small gaps remain at the host–allograft junctions, grafting can be performed. Usually cancellous bone can be curetted from unused allograft for this purpose.
- The wound is closed in layers over suction drains.
- Efforts should be made to obtain circumferential muscle coverage over the reconstructed bone.
- A gentle compression dressing is placed. Splinting of the knee may improve patient comfort for the first few postoperative days.

**VASCULARIZED FIBULAR GRAFT**

- Vascularized fibular grafts are used to supplement intercalary allografts, improving healing and adding strength and living bone to the reconstruction.
- Vascularized grafts add complexity and time to the operative reconstruction.
- Vascularized graft can be harvested from the ipsilateral or contralateral leg.
- In the femur, vascularized grafts can be placed medial or lateral, bridging across the allograft and affixed to the proximal and distal host segment.
- In the tibia, soft tissue constraints often require the vascularized graft to be placed within the allograft. A groove made in the allograft facilitates placement of the vascular graft.
- For a more complete explanation of this procedure, see Chapter ON-28.

**TIBIA, HUMERUS, AND FOREARM**

- Reconstructions in the tibia, humerus, and forearm are similar.
- Intramedullary fixation may be possible in the tibia and humerus.
- Plate fixation for the humerus and tibia should be done with 4.5-mm plates.
- Plate fixation in the forearm is performed with 3.5-mm plates.
- Special locking plates designed for the proximal tibia are often useful in tibial reconstructions.
- Care must be taken in the radius to recreate the radial bow.

**INTERCALARY ENDOPROSTHETIC RECONSTRUCTION**

- After tumor resection, frozen sections of the remaining medullary contents are performed to ensure margins are free of tumor.
- Careful measurement of the specimen length is necessary to ensure proper selection of components (if using a modular system).
- Preparation of the bone canal is critical to ensure adequate fixation; use of rigid instead of flexible intramedullary reamers is preferred to obtain best fit of the prosthetic stem.
- C-arm fluoroscopy is used to monitor the reaming process to avoid penetration into the adjacent joint.
- Facing reamers are used to machine the proper radius of curvature of the exposed cortical bone to ensure flush fit of the implant's stem–body junction.
- Trial reduction is performed to check length and rotation and to ensure that reduction of the prosthesis bodies is possible; the specific connection between the proximal and distal bodies varies depending on the implant manufacturer.
- For implants with cemented stems, proper canal preparation using cement restrictors, pulsatile lavage, and packing for hemostasis is performed before injection of cement and impaction of the stem.
- Uncemented systems may require further canal preparation; Compress™ implants use a number of interlocked jigs for centralization of the intramedullary anchor plug and placement of transfixion pins through the adjacent cortical bone.
- Final assembly of the prosthesis is performed per implant requirements; care must be taken to ensure that rotation is proper and that all locking mechanisms are tightened or impacted.
- Supplemental bone graft, collected during reaming, is placed at the implant–bone junction (over the porous coated surface) to provide extraskeletal fixation of the implant.
- Soft tissue reconstruction over closed suction drains is then performed. When necessary, local rotation flaps are used to ensure muscular coverage of the implant.
**POSTOPERATIVE CARE**

- Proper wound healing is critical to avoid infection of the reconstruction; use of antibiotics during the perioperative phase is extremely important, particularly with allograft reconstructions.
- Allograft patients are maintained on touch-down weight bearing until healing of the host–allograft junctions is seen radiographically (usually 3 to 12 months).
- Additional bracing is necessary only if a stable construct is not obtained. This can occur in plate reconstructions with small residual host segments after resection.
- Physical therapy should be directed toward range of motion of the hip and knee. Muscle strengthening can be performed with minimal resistance as dictated by the stability of the construct achieved in surgery.
- Intercalary implants permit immediate weight bearing; short-stemmed components around the knee are protected by placing the patient in a knee immobilizer and limiting joint range of motion to gentle assisted exercises under supervision during the initial healing stages.

**OUTCOMES**

- Most studies report combined results for intercalary, osteoarticular, and allograft prosthesis composites.
- Nonunion rates are reported to be 10% to 15%.
- Late fracture rates are reported to be 7% to 20%.
- Union rates with nails and plates are nearly equal, but the late fracture rate is higher with plates.
- Functional outcomes are reported as 78% to 86% good or excellent.
- Graft survival is reported as 79% at 5 years.
- Few reports of intercalary implants have been published; individual institutional experience has been very favorable, with 100% implant survival and near to complete functional restoration of the limb.

**COMPlications**

- Nonunion of the allograft–bone junction frequently occurs and may be treated with secondary bone grafting or allograft revision. Use of vascularized fibular grafts in high-risk patients should be considered to minimize this complication.
Infection is the most common cause of allograft and prosthetic failure and can lead to secondary amputation. Aggressive surgical débridement with removal of all foreign bone or materials is necessary.

Late fracture of massive allografts can lead to chronic pain and loss of function. Use of intramedullary fixation and avoiding screws in the allograft may help to minimize this complication.

Prosthetic loosening rarely if ever occurs for intercalary implants. Implant failure can be revised with use of a new prosthesis.

Degeneration of an adjacent joint after either allograft or intercalary implant reconstruction can be treated with surface-replacing total joint arthroplasty.

REFERENCES

BACKGROUND

The quadriceps muscle group is the most common site for extremity soft tissue sarcomas.

The most common sarcomas at this site are liposarcomas, malignant fibrous histiocytomas, and leiomyosarcomas.

Although tumors of the anterior compartment of the thigh can be extremely large on first presentation, it is possible to perform limb-sparing resections in most patients. By using induction chemotherapy to shrink the lesion and postoperative adjuvant radiation therapy to eradicate possible residual microscopic disease, resections of the anterior compartment of the thigh are often safe and reliable.

In addition, when resection necessitates en bloc removal of a considerable amount of muscle tissue, reconstruction of the extensor mechanism with the sartorius muscle, the hamstring muscles, or both produces good functional results.

The most common indications for amputation (ie, modified hemipelvectomy) are large tumors with extracompartmental extension into the adductor and hamstring musculature, tumors with intrapelvic extension through the femoral triangle and inguinal ligament, large fungating tumors, and massive tumor contamination, with or without infection.

INDICATIONS

Almost all low-grade soft tissue sarcomas of the anterior thigh may be safely resected by a partial muscle group resection. The large majority of high-grade soft tissue sarcomas can be resected by partial or total compartmental removal. The contraindications to limb-sparing resection are as follows:

- Groin involvement. Tumors arising or involving the groin and femoral triangle often cannot be reliably resected and may require amputation.

- Extracompartmental extension. In general, resection of a single muscle group permits a viable extremity. If two muscle groups have to be completely removed, the extremity may not be functionally salvageable. Large tumors of the anterior thigh may involve the adductor group as well as the posterior muscle group by passing through the linea aspera or the intermuscular septum. In this situation amputation might be necessary.

- Intrapelvic extension. On rare occasions, large tumors of the proximal thigh and groin extend below the inguinal ligament into the retroperitoneal space, necessitating amputation.

- Recurrent tumors of the quadriceps, infection, extensive tumor hemorrhage, or extensive tumor contamination from previous surgical procedures may require amputation.

- Neurovascular involvement of the tumor does not necessarily obviate limb-salvage resections. Most tumors of the quadriceps muscle will displace but not invade the superficial femoral or common femoral arteries. If the surgical margins are positive for tumor cells or extremely close, resection of the involved artery and replacement with a vascular graft often allows limb salvage.

- Femoral nerve sacrifice is also not a contraindication for limb-sparing resection; reconstruction techniques often permit knee extension and patellar stabilization, even when the entire quadriceps muscle is resected or paralyzed secondary to femoral nerve resection (Tables 1 and 2).

ANATOMY

The thigh consists of three distinct anatomic compartments, separated by thick fascial layers: the anterior compartment (quadriceps and sartorius muscle), the medial compartment (thigh adductor muscles), and the posterior compartment (the hamstring muscles).

The quadriceps muscle group consists of the vastus medialis, vastus lateralis, rectus femoris, and vastus intermedius muscles. The vastus medialis and lateralis arise from the proximal femur and intermuscular septum. The vastus intermedius arises from the surface of the femur and the linea aspera and covers the entire femoral shaft. The rectus femoris arises from the supra-acetabular tubercle at the superior part of the acetabulum. All four heads merge distally into the quadriceps tendon, which inserts onto the patella.

By covering the anterior aspect of the femur, the vastus intermedius protects the underlying femur from direct tumor extension by tumors of the other components of quadriceps muscle.

The fact that soft tissue sarcomas often remain localized to one muscle belly permits partial muscle group resection for many quadriceps sarcomas (FIG 1).

The medial and lateral intermuscular septum of the thigh separates the anterior thigh muscles from the medial and posterior compartments, respectively. However, the medial intermuscular septum “runs out” proximally, and quadriceps tumors may therefore extend into the posterior and medial compartments and complicate and sometimes obviate a limb-sparing resection. Likewise, tumors arising from the medial and posterior compartments of the thigh may extend into the quadriceps group.

The femoral triangle is the key to resection of the quadriceps muscle group. It is formed by the adductor longus medially, the sartorius muscle laterally, and the inguinal ligament proximally. The pectineus muscle forms the floor of the triangle. A thick fascia covers the roof.

The superficial femoral artery and vein pass from below the inguinal ligament through the femoral triangle and into the sartorial canal at the apex. The femoral nerve enters the canal laterally and quickly branches to innervate the quadriceps muscle components. The superficial femoral artery and vein pass along the medial wall of the sartorial canal throughout the length of the thigh and are separated from the anterior group (vastus medialis) by a thick fascia, which often permits a safe resection.

This fascia forms a good border for quadriceps resections.

Unique Anatomic Considerations

An important criterion for the success of a muscle flap transfer (FIG 2A–D) is maintenance of a pattern of circulation that...
is consistent in location and resistant to the effect of radiation therapy and superficial trauma (FIG 2E). The surgical manipulation of the muscle flap must not interrupt its circulation; therefore, a precise knowledge of the location and pattern of the vascular pedicles is required. The sartorius muscle is supplied by the superficial femoral artery and has a segmental vascular pattern (type IV vascular pattern according to Mathes and Nahai6). Each pedicle provides circulation to a portion of the muscle, and division of more than three pedicles during the elevation of the flap may result in distal muscle necrosis. The hamstring muscles are supplied by branches of the profunda femoris artery and have proximal dominant vascular pedicles and distal minor pedicles (type II vascular pattern). Complete elevation of the muscles is possible when the dominant proximal vascular pedicles are preserved.

IMAGING AND OTHER STAGING STUDIES

Computed Tomography and Magnetic Resonance Imaging
- Magnetic resonance imaging (MRI) and computed axial tomography (CAT) are essential for determining the location and extent of the lesion and its relations to the femoral bone, respectively.
- Tumors may remain within one muscle belly or involve several components of the quadriceps muscle.
- It is important to identify the relationship between the tumor and the underlying femur. Tumors that involve the vastus medialis very often involve the adjacent periosteum as well.

Bone Scan
- A three-phase bone scan is useful to determine the proximity of the tumor to the periosteum. Absence of periosteal uptake indicates a reactive border or a pseudocapsule. This does not make quadriceps tumors unresectable but indicates that the underlying periosteum must be removed during the surgical procedure. Rarely does tumor extend directly into the bone.

Angiography and Other Studies
- Large tumors of the quadriceps muscle often displace the superficial and deep femoral vessels. It is important to determine the anatomic relations of these vessels to the tumor before resection. Large tumors of the proximal thigh may require ligation of the profundus femoris artery and vein; therefore, knowing before surgery whether the superficial artery is patent is essential. This is particularly true in the older patient, in whom the superficial femoral artery may be occluded secondary to peripheral vascular disease. Displacement of the superficial femoral artery usually does not indicate direct tumor extension; however, if the surgical margins are positive, the artery should be resected and replaced with a saphenous or artificial graft.

Biopsy
- The biopsy site should be in line with the planned incision for resection and must be located over the most prominent portion of the tumor. Core needle biopsy has been shown to provide reliable pathologic diagnoses and is our preferred method. Multiple samples can be collected from the same puncture site. Areas that major arteries and veins traverse should be avoided so that the vessels are not penetrated, risking tumor cell contamination.
A. Muscle transfers for type A resection (vastus lateralis with or without vastus intermedius). The long head of the biceps femoris is transferred anteriorly and sutured to the patella, the quadriceps tendon, and the rectus femoris muscle.

B. Muscle transfers for type B resection (vastus medialis with or without vastus intermedius). The sartorius muscle is transferred anteriorly but not detached from its distal insertion and is sutured to the patellar tendon, patella, quadriceps tendon, and rectus femoris muscle.

C. Muscle transfers for type C resection (rectus femoris and vastus intermedius). The sartorius muscle is mobilized anteriorly and sutured to the patella and the remains of the quadriceps tendon.

D. Muscle transfers for type D resection (subtotal resection). The biceps femoris laterally and the sartorius and semitendinosus medially are transferred anteriorly, tenodesed to each other, and sutured to the patella.

E. Vascular anatomy of muscles. There are five patterns of vascular supply to muscles, based on the distribution of major and minor vascular pedicles. The sartorius muscle has a type II vascular pattern and the hamstring muscles have a type IV vascular pattern (represented by the gracilis muscle in the schematic).
POSITION

- The patient is placed in the supine position with a bolster underneath the ipsilateral buttoc. If the tumor is close to or involves the femoral artery, the contralateral leg should also be draped for saphenous vein graft harvesting, in case the femoral artery needs to be resected (TECH FIG 1).

TECH FIG 1 • Type A resection (vastus lateralis and vastus intermedius) and reconstruction with biceps femoris transfer. Preoperative picture of a patient with a large malignant soft tissue sarcoma in the lateral aspect of the anterior compartment of the thigh. Resection includes the vastus lateralis and part of the vastus intermedius and rectus femoris. After completion of the resection, the lateral aspect of the femur is exposed. The long head of the biceps femoris is transferred anteriorly and sutured to the patella and the remains of the quadriceps tendon and rectus femoris.

LIMITED RESECTIONS OF THE QUADRICEPS MUSCLE

- Most tumors of the anterior compartment of the thigh are confined to one part of the quadriceps muscle and can be safely resected with negative margins without the need to sacrifice a considerable amount of muscle tissue.
- A longitudinal skin incision just above the tumor mass is made, encompassing the biopsy site. The tumor mass should be resected en bloc with 1 cm of surrounding healthy tissue.

- For tumors that involve the vastus medialis, vastus lateralis, or rectus femoris, the superficial margins are the skin and subcutaneous tissues and the deep margins may include part of the vastus intermedius. The superficial margins of tumors that involve the vastus intermedius may include part of one of the vasti or rectus femoris. If the deep surface of the tumor is close to the bone, the periosteum should be peeled off and resected and the superficial cortex removed with a high-speed burr (Midas).

PARTIAL OR COMPLETE QUADRICEPS RESECTION

- A long midline incision is made extending longitudinally from the anterior inferior iliac spine to the patella. It should be elliptical and should widely encompass the biopsy site (TECH FIG 2A).
- Flaps composed of skin and subcutaneous tissue are made just superficial to the fascia lata. They extend to the adductor muscle group medially and to the greater trochanter and flexor muscles laterally. The saphenous vein is divided as it enters the fossa ovalis. The inguinal ligament and the femoral triangle are uncovered, exposing the common femoral artery and vein and the femoral nerve (TECH FIG 2B).
- Lateral traction is placed on the quadriceps muscle group so that muscular branches coming from the superficial femoral artery and vein into the quadriceps muscle are exposed. Working from cranial to caudal, these vessels are clamped, divided, and ligated; included are the profunda femoris artery and vein. In the area of the canal of Hunter, while strong lateral traction is placed on the sartorius muscle, muscular insertions from the adductor magnus muscle coursing over the superficial femoral artery are identified. These muscular branches should be divided as they cross the superficial femoral artery (TECH FIG 2C,D).
- A plane beneath the tensor fascia lata muscle and above the gluteus medius and minimus is identified. By electrocautery the tensor fascia lata muscle is released from its origin on the wing of the ilium. Then the origin of the sartorius muscle on the anterior superior iliac spine is identified and divided. The origin of the rectus femoris muscle on the anterior inferior iliac spine is likewise identified and divided through its tendinous portion (TECH FIG 2E).
- The origins of the vastus lateralis, vastus intermedius, and vastus medialis on the femur are transected from the bone using electrocautery. Strong upward traction on the muscle group facilitates this dissection (TECH FIG 2F,G).
- Using strong upward and medial traction on the specimen, the insertions of the vastus lateralis, vastus medialis, and rectus femoris into the patellar tendon are divided on the patella (TECH FIG 2H).
- One cannot avoid transecting both the prepatellar and quadriceps (postpatellar) bursae. The insertion of the vastus medialis into the medial collateral ligament is likewise divided, and the specimen is then free. The dissection site is copiously irrigated, and any bleeding points are secured with ligatures or electrocautery.
TECH FIG 2 • A. The incision extends longitudinally from the anterior inferior iliac spine to the patella. It should be elliptical and should widely encompass the biopsy site. If physical examination or tomography shows that the tumor encroaches on the patella, this bone and its tendon should also be excised. If this clinical situation arises, the incision should be continued over the knee to the tibial tubercle. B. Cross-sectional anatomy. C. Flaps composed of skin and subcutaneous tissue are made just superficial to the fascia lata. They extend to the abductor muscle group medially and to the greater trochanter and flexor muscles laterally. The saphenous vein is divided as it enters the fossa ovalis. The inguinal ligament and the femoral triangle are uncovered, exposing the common femoral artery and vein and the femoral nerve. D. Dissection of the superficial femoral vessels. Lateral traction is placed on the quadriceps muscle group so that muscular branches coming from the superficial femoral artery and vein into the quadriceps muscle are exposed. Working from cranial to caudal, these vessels are clamped, divided, and ligated; included are the profunda femoris artery and vein. In the area of the canal of Hunter, when strong lateral traction is placed on the sartorius muscle, muscular insertions from the abductor magnus muscle coursing over the superficial femoral artery are identified. These muscle fibers should be divided as they cross the superficial femoral artery. E. Transection of muscle origins on the pelvis. A plane beneath the tensor fascia lata muscle and above the gluteus medius and minimus is identified. By electrocautery the tensor fascia lata muscle is released from its origin on the wing of the ilium. Then the origin of the sartorius muscle on the anterior superior iliac spine is identified and divided. The origin of the rectus femoris muscle on the anterior inferior iliac spine is likewise identified and divided through its tendinous portion. F. Resection includes the vastus lateralis and part of the vastus intermedius and rectus femoris. (continued)
G. Transection of muscle origins on the femur. Origins of the vastus lateralis, vastus intermedius, and vastus medialis on the femur are transected from bone by using electrocautery. Strong upward traction on the muscle group facilitates this dissection. H. Transection of the muscle insertions of the quadriceps muscle. Using strong upward and medial traction on the specimen, the insertions of the vastus lateralis, vastus medialis, and rectus femoris into the patellar tendon are divided on the patella bone. The insertion of the vastus medialis into the medial collateral ligament is likewise divided, and the specimen is then free. The dissection site is copiously irrigated, and any bleeding points are secured with ligatures or electrocautery. I. To facilitate rehabilitation by helping to provide stability to the knee, the gracilis muscle medially and the short head of the biceps muscle laterally are transected at their insertions on the medial and lateral collateral ligaments. This transection should be as far distal as possible so that a tendinous portion of the muscle is retained. Then, using heavy nonabsorbable sutures, these two muscles are transplanted onto the patellar tendon. The prepatellar and quadriceps bursae are closed within these sutures. The muscles are approximated in the midline to cover the distal third of the femur. J. After completion of the resection, the lateral aspect of the femur is exposed. K. Suction catheters are placed beneath the skin flaps and the subcutaneous tissue is approximated. The skin is closed and the incision is covered with povidone–iodine ointment and a loose dry sterile dressing. The patient may begin ambulation when the suction catheters have been removed and edema of the leg has resolved. Because the lymphatics along the superficial femoral artery and within the buttock remain intact, prolonged swelling is not usually a problem, serous drainage from transected muscle bundles does not occur in large amounts. The patient is ambulated initially with crutches and a touch-down gait.
If the tumor is close to the underlying femoral bone (TECH FIG 2I), the periosteum can be removed and the underlying bone exposed using a high-speed burr (Midas). Several millimeters of the outer cortex can be removed; however, the outer cortex itself should not be removed en bloc.

Suction catheters are placed beneath the skin flaps and the subcutaneous tissue is approximated with interrupted absorbable sutures. We recommend using 28-gauge chest tubes to drain the surgical space (TECH FIG 2K).

SOFT TISSUE RECONSTRUCTION OF RESIDUAL LARGE DEFECTS

If a significant amount of quadriceps muscle is resected or if the femoral nerve must be sacrificed, we routinely reconstruct the extensor mechanism to restore strength and balance patellar tracking. The long head of the biceps femoris muscle is used to reconstruct the lateral aspect of the quadriceps muscle (TECH FIG 3), and the sartorius muscle, the semitendinosus muscle, or both are used to reconstruct the medial aspect of the quadriceps muscle.

Another technique that can be used to functionally reconstruct large defects (which is not within the scope of this textbook) is latissimus dorsi microvascular transplantation. We believe it should be used whenever muscle transfers cannot be performed.

BICEPS FEMORIS TRANSFER FOR FUNCTIONAL RECONSTRUCTION OF LARGE LATERAL SOFT TISSUE DEFECTS

After completion of the resection, the long head of the biceps is transected from its insertion on the head of the fibula. This transection should be as far distal as possible to retain a tendinous portion of the muscle. The muscle is transferred anteriorly to the midline so that it will have an almost direct line of pull. Only a few deep perforating branches need to be ligated during this procedure. Due to the type II vascular pattern of the hamstring muscles, ligation of distal branches does not jeopardize its vitality. Then, using heavy, nonabsorbable sutures, the muscle is transplanted onto the patella and the remains of the quadriceps tendon and rectus femoris.

SARTORIUS AND SEMITENDINOSUS MUSCLE TRANSFER FOR FUNCTIONAL RECONSTRUCTION OF CENTRAL AND MEDIAL SOFT TISSUE DEFECTS

The sartorius, the semitendinosus, or both can be used to functionally reconstruct large medial defects. Large central defects are reconstructed with the sartorius muscle.

Semitendinosus Muscle Transfer

The muscle is transected as far distal as possible from its insertion to the proximal tibia and transferred anteriorly so that it will have an almost direct line of pull. Since the semitendinosus has a type II vascular pattern, ligation of its distal vascular branches for its mobilization does not compromise the vitality of the muscle. The muscle and its tendinous part are then sutured to the patella and the remains of the quadriceps.

Sartorius Muscle Transfer

After completion of the resection, the sartorius muscle is released, but not transected, from its distal insertion on the medial aspect of the proximal tibia. The aim is to transfer the muscle anteriorly to the midline to achieve a straight line of pull between its origin on the anterior superior iliac spine and the patella. After ligating only two or three distal vascular branches, the sartorius can easily be transferred toward the midline and sutured to the patellar tendon, the patella, and the remains of the quadriceps tendon. Since the sartorius muscle has a type IV vascular pattern, care should be taken not to ligate more than three vascular branches to prevent distal flap necrosis (Table 3).
POSTOPERATIVE CARE AND REHABILITATION

- Continuous suction is required for 3 to 5 days and perioperative intravenous antibiotics are continued until the drainage tubes are removed. If muscle transfer reconstruction was performed, a knee extension brace is initially used and an intensive physical therapy program for muscle strengthening and knee range of motion is started 3 to 4 weeks postoperatively. Weaning off the brace proceeds gradually, in accordance with the patient’s functional improvement.

- No immobilization is required if only resection was carried out, and patients may gradually begin ambulation when the suction catheters have been removed. Because the lymphatics along the superficial femoral artery and within the buttock remain intact, prolonged swelling is not usually a problem.

OUTCOMES

- Patients who undergo limited resections of the quadriceps muscle usually do not have any residual functional limitations. There are limited data regarding the functional outcomes of patients who undergo extensive resections of the quadriceps muscle with or without reconstruction.

- Markhede and Stener\(^5\) evaluated the postoperative function in 17 patients who underwent quadriceps muscle resections. They found that the isometric strength of the muscle decreased by 22%, 33%, 55%, and 76% when one, two, three, or more components of the quadriceps muscle were resected, respectively.

- Capanna et al\(^1\) reported on the functional effect of quadriceps resection combined with distal femoral resection and prosthetic reconstruction in patients with malignant bone tu-

F.N., femoral nerve.
mors. They concluded that the degree of quadriceps resection has a strong impact on functional outcome.

- Malawer performed a gait electromyographic analysis on a patient who underwent distal femoral resection, endoprosthetic replacement, and extensor mechanism reconstruction with the sartorius and biceps femoris muscles. Six months after the operation, both muscles were recruiting in phase with the rectus femoris of the same limb.
- According to our experience, most patients who undergo muscle transfer functional reconstruction have good to excellent functional outcomes and satisfactory active range of motion. Reported results of latissimus dorsi functional transplantation are likewise encouraging.

### COMPLICATIONS

- Wound dehiscence is usually associated with recent or ongoing postoperative radiation therapy and is easily managed by débridement and skin grafting.
- Vascular injuries rarely occur.
- Knee stiffness is the most common problem and is easily treated by physical therapy.

### REFERENCES

BACKGROUND

- The adductor compartment of the thigh is the second most common site for soft tissue tumors of the thigh, preceded by the anterior (quadriceps) compartment. Although resecting the muscular elements of this compartment does not considerably affect overall function of the lower extremity, the proximity of the major neurovascular bundle of the lower extremity requires special attention in the preoperative evaluation process and during tumor resection.
- Tumors arising within the adductor compartment are often extremely large at presentation. As they enlarge they often displace the superficial femoral and profundus vessels, and they may involve the extrapelvic floor musculature (obturator fascia) and bone (superior and inferior pubic rami and ischium) and even extend extracompartmentally to the medial hamstrings or the psoas muscle and the adjacent hip joint. These anatomic characteristics often make resection extremely difficult. Such large tumors were traditionally treated with amputation (i.e., hemipelvectomy). However, effective chemotherapy and radiotherapy regimens have allowed limb-sparing resections to be performed at that site with low rates of local tumor recurrence.
- Lipomas and low-grade liposarcomas, which are the most common tumor type at that site, are usually removed easily with their enveloping capsule without having to manipulate the vascular bundle. High-grade soft-tissue sarcomas, however, may grossly adhere to and surround the vascular bundle and require partial or complete resection of the involved bundle segment. Therefore, a limb-sparing tumor resection at that site begins with dissection and preservation of the superficial femoral vessels.
- Large high-grade sarcomas usually necessitate ligation of the profundus femoris artery. The surrounding adductors are then detached from their origin along the inferior and superior pubic rami and ischium and removed en bloc with the tumor. The soft tissue defect remaining after tumour resection is usually reconstructed by transferring the sartorius muscle and the remaining medial hamstrings.

ANATOMY

- The adductor compartment of the thigh consists of the adductor magnus, brevis, and longus, the gracilis muscles, and the major vascular bundle of the lower extremity. Compartmental muscles arise from the pelvic floor and the medial aspect of the ipsilateral pelvic ring (symphysis pubis, inferior pubic ramus, ischium, and obturator fascia) and attach distally to the linea aspera and the medial aspect of the distal femur.
- The superficial femoral artery passes along the anterior and lateral margins of the entire compartment and forms the lateral border. This compartment is best thought of as an inverted funnel, with the base being the obturator ring and fascia, the lateral border being the femur and linea aspera, and the tip of the cone being the adductor hiatus (FIG 1A,B).

- The bony structures of the pelvic floor are the closest margins for large sarcomas that arise within this muscle group. Occasionally, tumors arising from the pelvic ring require resection of the pelvic floor (type III pelvic resection) if negative margins are to be obtained in conjunction with a formal adductor group resection. Rarely, proximal adductor tumors may extend as a dumbbell around the ischium into the ischiorectal fossa. The possibility of such extension must always be evaluated preoperatively (FIG 1C).
- The medial hamstrings also take their origin from the ischium. There is no intermuscular septum separating the adductor group from the posterior hamstrings proximally; therefore, extracompartmental extension may occur between the adductor muscles and the medial hamstrings as these tumors enlarge proximally. Adequate resection may require partial medial hamstring resection.

INDICATIONS

- Benign soft tissue tumors of the adductor compartment
- Soft tissue sarcomas of the adductor compartment

CONTRAINDICATIONS

- In general, a combination of several contraindications is required, most of which are related to extremely large tumors. In those cases, we recommend induction chemotherapy or isolated limb perfusion and repeated staging studies before a definitive decision is made regarding amputation.2,3
- Contraindications to limb-sparing surgery include the following:
  - Major neurovascular involvement
  - Pelvic floor involvement
  - Extensive extracompartmental extension

IMAGING AND OTHER STAGING STUDIES

- Preoperative staging studies must evaluate the sartorial canal, pelvic floor, medial hamstrings, ischium, psoas muscle, and hip joint to determine the full extent of bone and soft tissue involvement.
- Plain radiographs, computed tomography (CT), and magnetic resonance (MR) imaging of the affected thigh, ipsilateral hip joint, and hemipelvis are indicated.
- Most adductor tumors displace the superficial femoral vessels but rarely directly involve these structures (FIG 2). The profundus femoris artery, on the other hand, is often involved and must be ligated as it passes through the adductor brevis. The obturator artery and nerve, which pass through the obturator fascia, are routinely ligated.
- In light of the above, preoperative vascular evaluation of the patient should include direct questioning about intermittent claudication, limb swelling, and deep vein thrombosis. Vascular evaluation should include, in addition to physical examination, ankle–brachial pressure index and duplex ultrasound scanning.
FIG 1 • A. Anatomic structures of the adductor compartment. B. Cross-sectional anatomy of the adductor group. The sartorial canal is opened. C. Coronal section showing a dumbbell-shaped extension around the ischium into the pelvic cavity.

FIG 2 • A. Axial MRI showing a sarcoma of the adductor compartment. B. CT showing a large sarcoma of the proximal adductor compartment with displacement of the common femoral vascular bundle. Although the vessels are considerably displaced, a plane of dissection is evident between them and the tumoral mass.
of the femoral arteries and veins in the affected leg and of the greater saphenous vein in both legs.

- Underlying chronic obstructive arterial disease should prompt liberal use of angiography, CT angiography or MR angiography. Biplanar angiography, especially in patients older than 40, should be done to evaluate the patency of the superficial femoral artery: ligation of the profundus artery without a patent superficial femoral artery will lead to a non-viable extremity.

- In the past, angiography was also used preoperatively to outline the course of the vascular bundle within the affected thigh and to assess the likelihood of vascular reconstruction. High-definition MR scans provide the same useful information.

### INCISION AND EXPOSURE

- The incision extends from the proximal border of the inguinal region just inferior to the sartorius muscle and parallels the muscle to the posteromedial aspect of the knee to include the previous biopsy site (TECH FIG 1A). This incision permits large anterior and posterior flaps to be developed to visualize the vastus medialis, the sartorial canal, and the entire adductor compartment. The incision can be extended to expose the popliteal space medially if required. The superior extent may have to be T’d along the border of the inferior pubic ramus if there is a large soft tissue component extending to the obturator fossa and ischium.

- Large anterior and posterior fasciocutaneous flaps are elevated and retracted anteriorly to expose the vastus medialis and the sartorial canal and posteriorly to the lower edge of the adductor muscle group (TECH FIG 1B). The biopsy site is left en bloc with the underlying adductor muscles.

- The sartorius muscle is the key to the dissection of the entire muscle group. The sartorial canal is opened proximally to identify the common femoral artery before ligating the profundus vessels. The muscles are detached from their origin (superior and inferior pubic rami) and along the obturator foramen. The dissection continues from proximal to distal: the obturator vessels, then the profundus femoral vessels, are ligated and transected (TECH FIG 1C).

![TECH FIG 1 • A. The incision extends from the proximal border of the inguinal region just inferior to the sartorius muscle and parallels the muscle to the posteromedial aspect of the knee, to include the previous biopsy site. B. Large anterior and posterior fasciocutaneous flaps are elevated and retracted anteriorly to expose the vastus medialis and the sartorial canal and posteriorly to the lower edge of the adductor muscle group. C. Release of the adductor muscles from their insertions. The adductor magnus and longus are detached from their insertions on the femur throughout its length to the adductor hiatus. The adductor magnus tendon is then transected distally. A finger is inserted into the adductor hiatus to guide the cautery and protect the underlying vessels. (Courtesy of Martin M. Malawer.)](image)

### TUMOR RESECTION

- Low- and high-grade sarcomas, require en bloc removal of an overlying cuff of adductor musculature (TECH FIG 2A–C). Vascular involvement without a plane of dissection necessitates en bloc resection of the involved vascular segment (TECH FIG 2D–F).
VASCULAR AND SOFT TISSUE RECONSTRUCTION

- Resection of only a portion of the circumference of the artery for a short segment may be repaired by autologous vein patch. End-to-end anastomosis of a full circumferential resection is likely to be associated with considerable tension, and an interposition graft is required in those cases. Such reconstructions should be carried out with autologous tissue, primarily the greater saphenous vein (TECH FIG 3).
- It is best to use the vein from the contralateral thigh to preserve venous drainage as much as possible around the primary surgical site. This is particularly important if the femoral vein has to be ligated because of tumor extension around it or because of inadvertent injury. If the greater saphenous vein is inadequate or has been previously removed, the use of a prosthetic conduit is acceptable.
- An arm vein graft, although more time-consuming, is a better long-term solution. If the superficial femoral artery is chronically occluded, removal of the occluded segment is of no direct consequence. Careful intraoperative and postoperative evaluation of the profunda collaterals is mandatory; construction of a femoral...

TECH FIG 2 • A. Axial MRI of the midthigh showing a well-differentiated liposarcoma of the adductor compartment. B. The tumor is well encapsulated and can be safely removed with a narrow cuff of adductor musculature. C. Completion of tumor removal. The remaining structures to be transected are the insertions onto the distal femur, as well as portions of the gracilis muscle if required. The entire tumor is then removed and the wound is inspected. The superficial femoral artery and vein are inspected for any leaks. The cut edge of the muscles along the femur may be oversewn for hemostasis. If there is a large adductor tumor, occasionally a portion of the proximal medial hamstrings must also be removed en bloc. D. High-grade sarcoma of the adductor compartment extending into the superficial femoral vessels. Note the metal clip over the profundus femoral artery stump at the tumor bed. E. Blood vessels are suture-ligated and removed en bloc with the tumor. F. Gross surgical specimen. (C: Courtesy of Martin M. Malawer.)
Preoperative imaging of the entire adductor compartment and pelvic floor as well as detailed vascular evaluation

Full exposure of the vascular bundle before tumor resection

En bloc resection and reconstruction of affected vascular segments

Prophylactic calf fasciotomy if arterial reconstruction and venous ligation were done

Postoperative care

Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. Full weight bearing is allowed as tolerated.

Outcomes

Resections around the adductor compartment are usually associated with minimal loss of function. Limb edema, however, may occur in patients who had vascular reconstruction and venous ligation. Adjuvant radiation therapy also increases the likelihood of chronic limb edema, which can be managed with lymphatic drainage.

Patients who require a vascular reconstruction have similar rates of local tumor control and systemic relapse compared with patients who have not. However, these patients have higher chances of wound complications and deep vein thromboses.1

Complications

Deep wound infection

Vascular insufficiency

Deep vein thrombosis

Flap ischemia

Local tumor recurrence

References

BACKGROUND

- The posterior thigh (hamstring musculature) is the least common of the three compartments of the thigh for sarcomas to arise within. About 15% to 20% of the soft tissue sarcomas of the thigh arise within the posterior hamstring musculature. There is great variation in the size of tumors that occur in the posterior thigh, and the location varies from a proximal location near the ischium to a distal location involving the popliteal space. The posterior thigh is a quiet surgical area; the most significant structure is the sciatic nerve. Almost all low-grade sarcomas can be resected safely. Most high-grade sarcomas can be resected by either a complete or partial muscle group resection. The sciatic nerve is rarely involved, either because of direct tumor extension or because of a primary nerve tumor.
- En bloc resection of the sciatic nerve with a malignant tumor of the posterior thigh rarely is done; this has traditionally been considered an indication for amputation. This approach was based on the belief that the expected motor and sensory loss around the leg and foot would result in an intolerable functional deficit and the development of pressure sores and, therefore, high rates of secondary amputation. However, it has been shown that limb-sparing resection of the sciatic nerve is associated with a good functional outcome in most patients who have this procedure. Most patients were ambulatory; all used a short-leg brace because of the peroneal nerve palsy, but only half required a walking aid (crutches or a cane).  

ANATOMY

- The posterior compartment consists of the semimembranosus, the semitendinosus, and the long and short heads of the biceps muscles. All of these muscles originate at the ischium and the linea aspera. No major artery is involved with this compartment.
- The sciatic nerve is the most significant structure. It runs from the sciatic notch into the compartment from lateral to the ischium and divides the medial and lateral hamstrings. A thick sheath surrounds the nerve, acting as a barrier to direct tumor extension. Often tumors arise within one of the individual muscles of the posterior thigh or between the muscles. In most cases the sciatic nerve is displaced around an adjacent muscle.

INDICATIONS

- Almost all low-grade sarcomas of the posterior thigh can be treated by partial or total resection of the involved muscle. High-grade sarcomas are treated by complete myomectomy of the muscle involved. If the tumor is extramuscular but still remains within the compartment, a partial muscle group resection is performed (FIG 1). Multiple muscles or the entire compartment can be resected instead of an amputation.
- Contraindications for limb-sparing resections of the posterior compartment include:
  - Extension into ischiorectal space: This makes the resection more difficult and may indicate the need for an amputation.
  - Extension into the popliteal space with vascular compromise
  - Femoral involvement with cortical destruction

IMAGING AND OTHER STAGING STUDIES

- Preoperative evaluation must include the ischium, the ischiorectal space, the retrogluteal area, and the popliteal space for tumor extension. The most useful imaging studies are computed tomography (CT) and magnetic resonance imaging (MRI). Angiography is required only if tumor extends distally into the popliteal space (FIG 2).

FIG 1 • Cross-sectional anatomy of the midthigh showing the extent of compartmental resection of the posterior thigh. The proximity of the sciatic nerve to large sarcomas within the posterior compartment is clearly indicated. (Courtesy of Martin M. Malawer.)
FIG 2 • Axial (A) and coronal (B) MR images of a myxoid liposarcoma of the posterior thigh. The tumor is extramuscular, arising in the space between the medial and lateral hamstrings. Clinical picture (C) and axial MR image (D) of a high-grade neurofibrosarcoma of the posterior thigh in a patient with an underlying neurofibromatosis. Café-au-lait spots are present on the patient’s thigh. This is a primary tumor of the sciatic nerve and must be removed to obtain wide margins of resection.

POSITION AND DISSECTION

- The patient is placed in a prone position. A long midline incision is used. An ellipse of skin is outlined so that there is a 2-cm margin of skin around the old biopsy site. The skin flaps are dissected, with care being taken to taper the flaps as one encounters the lateral margins of the dissection. The medial extent of the dissection is the gracilis muscle, and the lateral extent is the iliotibial tract (TECH FIG 1A,B).

TECH FIG 1 • Illustration (A) and clinical photograph (B) showing the surgical incision. The extent of the tumor is outlined. (continued)
SKIN FLAPS AND EXPOSURE

- The medial (semitendinosus and semimembranosus) and lateral (long and short heads of biceps femoris) muscles are exposed (TECH FIG 1C). The extent of the dissection is determined by the location of the tumor, but it generally involves the long head of the biceps femoris, the semimembranosus, and the semitendinosus (TECH FIG 1D–F). It is possible for part of the lateral quadriceps mechanism to be included with the specimen.

- Likewise, one or more muscle bundles of the adductor muscle group may be included if this will afford a more generous margin. The three muscles mentioned, which originate from the ischial tuberosity, are superficial to the sciatic nerve. With a tumor-free margin of resection on a tumor-free plane superficial to the posterior limits of this compartment, it is clear that the next adjacent structure is the sciatic nerve itself.

TUMOR REMOVAL

- Benign and low-grade extramuscular tumors can be removed with their enveloping capsule (TECH FIG 2A). High-grade sarcomas or tumors that involve muscles of the posterior compartment, however, require en bloc muscle resection.

- Dissection begins by exposing the ischial tuberosity. It is easily identified on the skin surface. The hamstring muscles are released at their origin from the ischial tuberosity (TECH FIG 2B). Traction is then placed on the muscle group, which is secured with a clamp. Blood ves-
A. The extramuscular liposarcoma shown in Techniques Figure 1F can be safely removed without adjacent muscle tissue. B. Dissection and release of the hamstrings origin is the first stage of tumor removal. C. Tumor mass and enveloping muscles are elevated from the sciatic nerve and the base of the compartment by blunt and sharp dissection. D. Tendinous insertion of the biceps femoris muscle on the lateral aspect of the thigh is transected. E. Sciatic nerve is grossly surrounded by high-grade sarcoma of the posterior compartment. No plane of dissection exists, and resection of the sciatic nerve is mandatory to achieve wide margins of resection. F. Tendinous insertion of the medial hamstrings is transected. (B–D,F: Courtesy of Martin M. Malawer.) (continued)
G. Photograph of the posterior thigh after resection of an extramuscular liposarcoma. Posterior thigh musculature is preserved and retracted, and the tibial and common peroneal nerves are seen underneath. H. Posterior thigh after en bloc resection of a high-grade sarcoma with the overlying muscles and the sciatic nerve; only the semimembranosus muscle is left in the surgical field.

By blunt and sharp dissection, the sciatic nerve, the short head of the biceps laterally, and the adductor muscles medially are elevated from the base of the dissection (TECH FIG 2C). The lateral muscle insertion is then transected. The long head of the biceps femoris muscle is transected through its tendinous portion on the lateral aspect of the thigh. Care should be taken to avoid injury to the common peroneal nerve (TECH FIG 2D).

If tumor grossly involves the sciatic nerve with no plane of dissection, the nerve is then resected (TECH FIG 2E). The insertions of the semimembranosus and semitendinosus muscles are then divided through their tendinous portion medially. The medial head of the gastrocnemius muscle is exposed (TECH FIG 2F–H).

The superficial fascia and skin are meticulously closed. Generous suction drainage is applied. The suction drains should not exit through the skin flaps, but just above the gluteal crease (TECH FIG 3).

The superficial fascia and skin are meticulously closed. Generous suction drainage is applied. The suction drains should not exit through the skin flaps, but just above the gluteal crease (TECH FIG 3).

PEARLS AND PITFALLS

| Preoperative | Imaging of the posterior compartment, ischium, and ischiorectal space |
| Intraoperative | Long midline incision |
| Postoperative | Use of short-leg brace and passive range-of-motion exercises |

A short-leg brace is applied and passive range-of-motion exercises are practiced immediately after surgery to avoid Achilles tendon shortening. Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. Full weight bearing is allowed as tolerated.

OUTCOMES

Function after posterior thigh resection is almost normal: knee flexion is maintained by the remaining sartorius, gracilis, and gastrocnemius muscles.

Most patients who underwent en bloc resection of the sciatic nerve with a tumor of the posterior thigh were ambulatory; only half required a walking aid. All used a short-leg
brace because of the loss of the peroneal nerve. Padded shoes are used to prevent pressure sores.

Although all patients have an anesthetic ipsilateral foot, phantom limb pain, causalgia, pressure sores, and secondary amputation have not been documented. It seems that patients who had resection of the nerve at a lower anatomic level have better functional outcomes than patients whose resections involved a higher level. A possible explanation is that the innervation to the semimembranosus, semitendinosus, and long head of the biceps femoris is preserved in lower-level resections.

**COMPLICATIONS**

- Deep infection
- Flap ischemia and necrosis
- Sciatic nerve partial to complete dysfunction
- Local tumor recurrence

Chapter 33

Overview of Surgical Resection of Space Sarcomas

Amir Sternheim, Tamir Pritsch, and Martin M. Malawer

BACKGROUND

- The three main extracompartmental spaces of the lower extremities are the femoral triangle, the sartorial canal, and the popliteal space. Each of these spaces is defined by the bordering compartments of the lower extremity.
- All extracompartmental spaces have walls comprising the muscles and their fascia of the neighboring compartment, lumen, that is filled with fat, fibrous tissue, and vessels that transverse the space, mainly arteries, veins, and nerves.
- The distinction between intracompartmental and extracompartmental spaces was introduced by Enneking in his classification of soft tissue tumors as part of the Musculoskeletal Tumor Society (MSTS) surgical staging system more than two decades ago. Enneking borrowed the term “extracompartmental” from his classification of bone tumors. In that context, it refers to tumors that originate in the bone and then breach the cortex and have a soft tissue component.
- Extracompartmental tumors were considered to be more aggressive than their intracompartmental counterparts and therefore harder to treat and with a worse prognosis, although this has changed in recent years.
- The original soft tissue sarcoma (MSTS) staging system had three prognostic criteria: metastasis, grade, and compartmentalization.
- The term “compartmentalization” divides soft tissue sarcomas into intracompartmental and extracompartmental tumors. Intracompartmental lesions are bound in all directions by natural barriers such as bone and muscle. These tumors arise within a structure—thigh: anterior, adductor, posterior; leg: anterior, peroneal, posterior superficial, posterior deep.
- In contrast, extracompartmental tumors either arise in spaces that are not bound by tight muscle fascia as compartments are (ie, popliteal space, sartorial canal, femoral triangle, axilla, antecubital fossa, paraspinal, intrapelvis, thigh, midfoot, and hindfoot) or develop secondary to the extension of an intracompartmental tumor beyond the confines of a compartment.
- Extracompartmental tumors have unique characteristics. They can extend a considerable distance with less anatomic restraint. They tend to be larger than their intracompartmental counterparts and frequently arise close to the neurovascular bundle. For these reasons, space tumors were initially considered to have a poorer prognosis than those confined to a compartment at diagnosis. Newer prognostic studies of soft tissue sarcomas do not support the assumption that space tumors have a worse prognosis due to their location but rather due to their size.
- Space tumors have been poorly addressed in Enneking’s classification and in the later American Joint Committee on Cancer (AJCC) classification. The classification of an intracompartmental lesion was based on tumor biology. Extracompartmental tumors were originally tumors that grew from within a compartment outward and into an adjacent compartment. Only later was the definition broadened to include space tumors. Since then, these space tumors have been poorly discussed in terms of their anatomy, biology, and surgical approach.
- The newer version of the AJCC classification for the staging of soft tissue sarcomas does not use compartmentalization as a staging criteria but rather tumor grade, size, and depth.
- Resection goals for soft tissue sarcomas of the extremities are wide resection of the lesion with negative resection margins and satisfactory extremity function.
- With intracompartmental tumors, these goals are achieved by resecting the tumor with the muscle that surrounds it. Space tumors lie in proximity to vessels and nerves, so achieving wide resection of the tumor without resecting the vessels is a delicate task.
- Some tumors, although in intimate proximity to the vessels, may still be resected with negative margins, whereas other tumors behave differently and invade the vessels. Vessel invasion dictates vascular resection. This biologic difference in tumor behavior is dictated by tumor grade, size, and histology and the anatomic location in the space from which it arises.
- Different tumors, due to their different biology, dictate different surgical resection techniques. Unlike intracompartmental tumors, space tumors differ vastly from one tumor to the next in the amount and technique of resection needed. Guidelines for resecting the different types of space tumors are lacking.

ANATOMY

Femoral Triangle Space

- The femoral triangle can be depicted as a three-dimensional pyramid. The base is the inguinal ligament, bound laterally by the sartorius and medially by the medial edge of adductor longus or the anterior border of gracilis (FIG 1).
- The floor of the femoral triangle is the iliopsoas laterally and the pectineus and adductor longus medially. Its apex is where the sartorius crosses over to the adductors.
- The main vessels traversing the canal are, from medial to lateral, the femoral vein, artery, and nerve. They enter the femoral triangle from the abdomen under the inguinal ligament and exit it distally from the tip of the pyramid into the sartorial canal.

Sartorial Canal

- The sartorial canal lies between the anterior (quadriceps) compartment and the medial adductor compartment, connecting the tip of the femoral triangle in the proximal thigh to the popliteal fossa in the distal posterior aspect of the thigh. The cross-section of the sartorial canal is shaped like an inverted triangle (FIG 2).
- The roof of the canal is made up of the sartorius muscle, which lies anterior and medial to the canal. The adductor longus makes up the floor of the canal. The lateral border is the thick fascia of the vastus medialis. Posteriorly, the border...
FIG 1 • Cross-sectional anatomy of the lower extremity spaces. A. Femoral triangle anatomy follows the general outline of a three-dimensional pyramid. The vessels within the space from medial to lateral are the femoral vein, artery, and nerve. The femoral triangle has as its base the inguinal ligament; it is bound laterally by the sartorius and medially by the medial edge of adductor longus and the anterior border of gracilis. The floor of the femoral triangle is the iliohypogastric laterally and the pectineus and adductor longus medially, and its apex is where the sartorius crosses over to the adductors. B. Popliteal space anatomy follows the general outline of a three-dimensional diamond shape. The biceps femoris, semimembranosus, lateral gastrocnemius, and medial gastrocnemius muscles form the four walls of the space. The popliteal artery and vein lie deep in the space, while the sciatic nerve is more superficial. The deep fascia serves as a barrier between the space and the superficial tissue.

Popliteal Space
- The popliteal space is shaped like a three-dimensional diamond. On its proximal lateral side is the biceps femoris muscle. On the proximal medial side are the semitendinosus and semimembranosus muscles. On the distal side of the space are the lateral and medial heads of the gastrocnemius muscles (see FIG 1B).
- Anterior to the space is the posterior capsule of the knee joint. Posterior to the space is a thick popliteal fascia.
**Vessels of the popliteal space are the popliteal artery and vein, which enter proximally through the adductor hiatus and exit distally between the two heads of the gastrocnemius.**

**The sciatic nerve enters the space through the proximal tip and divides into the peroneal and tibial nerve branches.**

**INDICATIONS**

A set of surgical guidelines is a helpful clinical conceptual tool in resecting lower extremity soft tissue sarcomas from the three anatomic spaces. Using preoperative MRIs and initial intraoperative impressions, tumors may be divided into three groups.

Tumors are divided according to their location of origin.

- Type 1 tumors arise from within the space. Typically they originate from fat or fibrous tissue within the space. These tumors are termed “luminal” because they may approximate but do not adhere to the walls of the space or any of the arteries, veins, and nerves in the space. They lie within the lumen.
- Type 2 tumors arise from one of the walls that border the space. These tumors arise from within a muscle or the muscle fascia that borders the space.
- Type 3 tumors invade the arteries, veins, or nerves and are termed vessel lesions. These lesions either originate from or invade the vessels walls.

The surgical planes of resection differ for each of the three types:

- Type 1 (luminal) lesions are resected with a thin cuff of healthy tissue that surrounds the tumor. At times these tumors almost deliver themselves once the space is opened. Tumor margins, although negative, are often close.
- Type 2 (wall) lesions are essentially resected with the muscle from which they originate. Wide surgical resection is achieved by resecting the tumor with its muscle of origin and the fascia covering that muscle.
- Tumors that approximate the vessels and are adherent to the vessel sheath are resected with the vessel sheath as an oncologic barrier and should be approached in the following manner. On approaching the tumor area, if the sheath appears free and separates easily from the wall of the artery, the surgeon continues the dissection, leaving the sheath attached to the surface of the specimen by making an incision in the sheath on the side away from the tumor and extricating the artery (and vein if possible) from its sheath.
- The fibrous sheath surrounding the vessels is inspected carefully on frozen section after it has been removed en bloc with the tumor. Even when the tumor does not adhere to the vessel sheath, it should be removed separately from the tumor so that it can be examined to rule out tumor invasion through the sheath, thus ensuring safe resection margins.
- Type 3 (vessel) tumors are imbedded in the vessel wall. When it is clear that the vessels are involved, the surgeon establishes vessel control proximally and distally and works around the tumor widely all the way around until the soon-to-be specimen is tethered by the vessels proximally and distally. The surgeon then chooses the grafts to be used, administers heparin, and applies vascular clamps proximally and distally. The specimen is removed, followed by reconstruction.

- This circumferential freeing of the tumor and the normal tissue margin is the essential difference between space tumors involving the vessels and those not involving them, a difference in surgical strategy.
- After the artery is resected it must be reconstructed with a synthetic graft or a reverse saphenous vein graft. Venous resection does not need to be reconstructed as long as the ipsilateral saphenous vein is intact. Potential morbidity from venous resections arises from the risk of edema in the affected limb. Nerves invaded by tumor must be resected en bloc (namely, sciatic, femoral, tibial, and peroneal). These nerve resections do not dictate a need for amputation but can be treated with limb-sparing surgery. As the tumor is resected en bloc with the vessel, these resections, while challenging surgically in their reconstructive aspects, are relatively straightforward in their tumor resection aspects and can achieve wide surgical margins.

**IMAGING AND OTHER STAGING STUDIES**

Plain Radiography

Plain radiography studies are performed to rule out local invasion of the bone by the tumor.

Computed Tomography and Magnetic Resonance Imaging

These studies are used to assess the anatomic location and size of the tumor and its relation to surrounding structures. These studies are particularly important since the tumor often distorts the normal anatomy in these small, tight spaces. Arterial contrast and three-dimensional reconstruction enhance these studies even further.

MRI is useful in assessing the tumor’s invasion into neighboring anatomic structures, namely the muscles bordering the canal and the vessels traversing the canal.

Bone Scan

Bone scan is used to rule out distant metastatic disease and may give a clue to the malignancy of the tumor, as high-grade tumors show a strong tumor blush in the late arterial flow phase of the three-phase technetium scan.

Angiography and Other Studies

Angiography is used to assess the vascularity of the tumor, tumor blush, the location of the vessels feeding the tumor, and the relation between the tumor and the major artery and vein, giving vital information as to whether the tumor has displaced or invaded the vessel.

Venography of the limb is used to rule out venous thrombus, tumor thrombus, or direct tumor involvement.

**Biopsy**

- Core needle and open incisional biopsy give vital information about the tumor. The proximity of these tumors to major vessels adds an additional risk factor for both iatrogenic damage to the vessels and contamination of the space with tumor cells due to hematoma. We prefer a small needle biopsy and a fine-needle aspiration. It is most important to determine whether the tumor is a lymphoma or a mesenchymal tumor (soft tissue sarcoma).
- Lymphomas do not require surgical resection. The exact histogenesis is not required if it is a soft tissue sarcoma, because
resection margins are usually more defined by the anatomy than the actual surgical procedure. However, it is important to determine the grade (high or low) because neoadjuvant chemotherapy may be recommended.

SURGICAL MANAGEMENT
- Wide exposure of the space is critical. The space must be unroofed by retracting and at times detaching the overlying muscle.
- Initially critical vessels should be identified and controlled proximally and distally to the tumor, where the anatomy has not been distorted.
- Tumor is resected in a circumferential manner with wide margins when possible. When the lesion is in intimate proximity to the vessels, the sheath of fibrous tissue surrounding the vessels should be resected en bloc with the tumor unless it is evident that it has not been invaded. The vessel sheath should be opened from the opposite side of the tumor to assess whether tumor that adheres to the sheath has invaded the vessel wall as well.
- Tumor that invades the vessels must be resected with the vessels, which then need to be reconstructed.
- When the tumor does not seem to grossly invade the vessels, the sheath that has been resected en bloc with the tumor should be examined on frozen section to rule out microinvasion.
- Soft tissue reconstruction is done by moving adjacent muscle to cover the vessels. This is essential. If there is later wound breakdown, the vessels must have good vascularized soft tissue coverage.

Preoperative Planning
- Preoperative MRI and CT and possible three-dimensional CT angiography are useful to identify the exact size and location of the tumor. This will help in classifying the type and thus in choosing the type of surgery that is required.
- Angiography is extremely important to determine accurately the position of the artery within the specific space. Often the artery is greatly displaced from the normal anatomic relationships. In the popliteal space, the artery is often displaced anterior to the tumor, whereas the sciatic nerve (tibial and peroneal branches) is often displaced in the opposite direction (ie, posteriorly and or laterally). In addition, the decrease in tumor blush from the initial angiogram and the final one after induction chemotherapy (for high-grade sarcomas) correlates well with the percentage of tumor necrosis. If there is a good angiographic response, then a marginal resection is very reasonable.

- Venography: The major veins may be occluded due to pressure of the soft tissue mass or invasion of the vascular sheath, and therefore by inference the major artery or nerves may be involved by tumor. Venous grafts are not performed because most will not remain patent.
- Neurologic examination: Involvement of a major nerve within a space often presents with severe pain or motor weakness. This should suggest to the surgeon that the major nerve may have to be sacrificed. In general, femoral nerve (femoral triangle) or sciatic nerve (popliteal space) involvement is not a sole indication for amputation.

Positioning
- Femoral triangle (space): A supine position is used. The abdomen and the thigh must be prepared together. It is often necessary to begin the exploration of the femoral vessels retroperitoneally to identify and to place a vascular loop around the external iliac artery and vein for proximal control.
- Sartorial canal: The patient is placed supine and the lower extremity is flexed and rotated externally at the hip. The entire thigh, lower pelvis, and leg are prepared so that the distal pulses can be palpated (or assessed using Doppler).
- Popliteal space: The patient is placed prone. The posterior thigh from above the gluteal crease to the foot is prepared free. This provides good exposure to the retrogluteal area, the posterior thigh (if the tumor extends proximal from the space), the popliteal space, and the leg (calf) if the tumor extends distal to the popliteal space, specifically below or between the gastrocnemius muscles.

Approach
- Femoral triangle: The incision begins proximal to the inguinal ligament as a gentle S and crosses the inguinal ligament. It then proceeds distal to the tip of the femoral triangle to the proximal portion of the sartorial canal. The incision somewhat parallels the medial border of the sartorius muscle. The major vessels are located proximal and distal before any attempted resection.
- Sartorial canal: The incision follows the sartorius muscle from the apex of the femoral triangle to the level of the adductor hiatus. If necessary, the incision may be extended to include the popliteal space (if the tumor is distal in the canal) or proximal (if the tumor is located proximal in the canal and extends into the femoral triangle). The sartorius muscle is mobilized either anteriorly or posteriorly along its borders (as long as the sartorius is not involved with tumor). Segmental pedicles to the sartorius muscle may be ligated. If the sartorius muscle is involved, then the muscle is transected proximal and distal to the tumor for exposure before resection.

TUMORS OF THE FEMORAL TRIANGLE
- The femoral triangle is exposed through a longitudinal incision that curves over the inguinal ligament and extends to the sartorial canal. The external iliac vessels (retroperitoneal) are exposed and a vessel loop is placed around them (TECH FIG 1).
- Wide subcutaneous skin flaps are made above the femoral triangle fascia to permit identification of the tumor, sartorius muscle, and adductor fascia.
- The proximal end of the sartorial canal is opened and the superficial femoral artery and vein are located to gain distal control.
- The deep fascia of the canal is opened, exposing the tumor.
- The tumor is explored and its surgical type is determined. Its relationship to the femoral nerve and femoral vessels is assessed. This will define which structures need to be resected and which can be preserved. If a vascular graft is required, either Gore-Tex or contralateral saphenous
vein can be used. If the femoral nerve is resected, medial and lateral hamstring transfers are performed at a second stage after wound healing or radiotherapy.

- The tumor is resected with surrounding fat, lymphatics, and any necessary muscle.
- Hemoclips are placed around the surgical bed.

TUMORS OF THE SARTORIAL CANAL

- The incision follows the course of the sartorius muscle. It may be extended proximally (femoral triangle) or distally (popliteal space) as required (TECH FIG 2).
- Wide subcutaneous flaps are elevated off the deep fascia to expose the anterior and posterior borders of the sartorius muscle.
- The sartorius muscle is then mobilized either along the anterior interval with the vastus medialis muscle or posteriorly along the adductor interval.
- If the sartorius muscle is not involved by tumor (based on the preoperative MRI), the muscle is usually preserved. The sartorial canal is explored both proximal and distal to the tumor mass to identify the superficial femoral artery and vein. If the saphenous nerve is encountered, it may be sacrificed.
- Tumor resection is then performed according to the type of tumor. Type 1 (intraluminal) tumors usually require only a simple marginal excision. If the tumor approaches the vessels, then the sheath is removed and sent for a frozen section examination. If no tumor is present at this margin, the sartorius flap is then closed.
- The sartorius muscle is routinely detached from the anterior superior iliac spine and rotated to cover the remaining defect and neurovascular structures. The sartorius muscle is tenodesed to the inguinal ligament and the remaining adjacent musculature. The skin flaps are then closed. A flat drain is placed deep to the muscle transfer.

TECH FIG 1 • Intraoperative image of a type 3 resection of a leiomyosarcoma arising from the femoral vessels. Proximal and distal control of the involved vessel is crucial. A vessel loop is placed on the external iliac artery (marked vessel). The spermatic cord is tagged and mobilized. A. The skin incision and the surgical approach follow the line of the inguinal ligament and sartorius muscle. B. The sartorius muscle is detached proximally to allow better exposure and soft tissue reconstruction. C. Soft tissue is reconstructed by fanning out the sartorius muscle, thus achieving a muscle barrier between the femoral vessels and the skin.

TECH FIG 2 • Type 2 resection of a tumor of the sartorial canal arising from the wall (vastus medialis) that comes in close proximity of the vessels. Even so, the tumor was resected and the vessels were spared, as it did not penetrate the fascial sheath surrounding the vessels. A. The skin incision is carried along the sartorius muscle. The sartorius is resected with the tumor if necessary from an oncologic point of view. If the tumor is not connected to the sartorius muscle it may be disconnected distally for exposure. B. Soft tissue reconstruction with a gracilis muscle transfer affords good soft tissue coverage of the vessels of the sartorial canal and is considered crucial. The distal end of the gracilis muscle is disconnected and rotated anteriorly. The muscle is then spread out like a fan and reattached anteriorly.
TECH FIG 3 • Large popliteal type 1 resection of a luminal tumor. Intraoperative picture shows wide exposure of the popliteal space. The tumor is in close proximity to the sciatic nerve above it and the popliteal artery and vein just below it (vessel loops). As it is a luminal tumor, resection with negative margins was achieved without resection of the surrounding vessels. A. Skin incision and subcutaneous flaps necessary to permit exposure. Care should be taken not to open the popliteal fascia while developing the flaps to reduce the risk of neurovascular injury. B. Release of the gastrocnemius heads, which are then reflected distally for maximal exposure. The popliteal vessels are identified distally between the gastrocnemius heads. C. Tenodesis of the heads of the gastrocnemius and the hamstring muscles, forming a muscular coverage over the popliteal vessels and nerves.

TUMORS OF THE POPLITEAL SPACE

- A “lazy S” incision is made over the popliteal space. The medial arm is always made along the medial border of the medial hamstrings because the popliteal vessels come into the space medially from the adductor hiatus (TECH FIG 3).
- The lateral arm of the incision is made along the lower border of the biceps femoris muscle because the peroneal nerve is initially picked up just below the deep fascia as a satellite of the biceps muscle.
- Wide subcutaneous flaps are made exposing the deep popliteal fascia. Great care is taken not to penetrate this fascia early because it is easy to get lost in the popliteal fat.
- The peroneal nerve is first identified just medial to the biceps muscle, just under the deep fascia.
- The deep fascia is then opened longitudinally and the sciatic nerve is identified between the medial and lateral hamstrings.
- The four muscles that make up the “diamond” of the popliteal space are now identified: the medial and lateral hamstrings proximally and the medial and lateral gastrocnemius muscles distally.
- The midline of the gastrocnemius muscles is identified. The popliteal vessels and the tibial nerve are mobilized and a vessel loop is placed around them for distal control.
- The sciatic nerve is then mobilized, both the peroneal and the tibial nerve components.
- The popliteal artery and vein are identified proximally near the medial hamstrings deep in the fossa as they enter from the adductor foramen. The surgeon can easily feel the pulse (a tourniquet should not be used), and a finger can be safely placed into the adductor hiatus for localization.
- Careful dissection and mobilization of the vascular and nerve structures are then performed.
- The medial or lateral head, or both, of the gastrocnemius muscles may be released from their origins on their respective femoral condyles to help in the exposure. Similarly, the semimembranosus or biceps femoris muscle may be released for better exposure.
- If the tumor extends proximally (between the hamstrings or distally between the gastrocnemius muscles), then the corresponding muscle must be released to obtain a wide excision.
- The popliteal vessels are usually displaced and not involved by tumor, unless a leiomyosarcoma is arising from them. In this situation a vascular graft is required.
- The tumor is resected only after all of the above structures are identified and mobilized. Sheaths of the adjacent nerves or vessels are removed and sent for frozen section examination to determine whether further resection is required.
- Soft tissue closure is necessary to cover and fill the popliteal space to prevent wound problems. The medial and lateral gastrocnemius heads are tenodesed to each other, covering the distal portion of the popliteal space and the neurovascular structures. Similarly, the medial hamstrings are tenodesed to the biceps femoris muscle to close over the proximal popliteal space. Both the gastrocnemius and the hamstrings are then sutured together to make a nice muscle closure of the entire popliteal space.
POSTOPERATIVE CARE
- Pulses are checked hourly for the first 24 hours.
- Drains are removed on postoperative day 2 or 3.
- Full weight bearing is permitted within 1 to 2 days.
- Minimal rehabilitation is required. Motion is limited according to the anatomic space for 7 to 10 days to permit complete wound healing. Popliteal incisions are protected with a bent-knee brace until the wound is well healed.
- Postoperative radiation therapy is started only after the wound is well healed, between 2 and 4 weeks.

OUTCOMES
- We have treated 53 patients with space tumors. Malignant fibrous histiocytoma and liposarcomas are the most common. A classification system was developed as described above. Most sartorial tumors tend to be of low grade and involve the wall; the sartorius muscle is most often involved.
- Liposarcomas and secondarily malignant fibrous histiocytomas were the most common histologic types. Tumors involving the wall of the space were more common than those that are intraluminal or those that arise from the major neurovascular structures. Tumors arising from the major vessels were leiomyosarcomas.
- Popliteal tumors, often high grade, can be dissected with negative margins and followed by radiation therapy. Sciatic nerve resection is very unusual.
- Amputation for all space tumors is needed in less than 10% of cases and is usually reserved for tumors that locally recur.
- The overall survival depends on the grade. Local recurrence is less than 10% for all sites. Radiation therapy is used for all high-grade sarcomas after wound healing.
- The surgical classification has been implemented on 53 patients with soft tissue tumors of the lower extremity spaces (femoral triangle, sartorial canal, and popliteal fossa).

COMPLICATIONS
- The most common problem is wound or flap necrosis. This is more common in the popliteal space. Incisions of the femoral triangle or the sartorial canal heal well.
- Neuropraxia, especially of the peroneal nerve, is common but, function almost always returns.
- Infection is unusual.
- Preoperative radiation is not used due to the risk of wound dehiscence or necrosis.
- Secondary amputations occur in less than 5% to 10% of patients, often after local tumor recurrence.

Chapter 34

Popliteal Resections

Jacob Bickels and Tamir Pritsch

BACKGROUND

- Soft tissue sarcomas of the popliteal fossa are rare, accounting for less than 5% of all soft tissue sarcomas of the extremities. Surgery in this anatomic area is challenging: performing a good resection with wide surgical margins is often difficult because of the periarticular location and the proximity to neurovascular structures.3,6,9
- Such tumors formerly were treated with amputations4; however, better understanding of tumor biology and advances in chemotherapy and radiation therapy now allow limb-sparing procedures to be performed in most of these cases.

ANATOMY

- The popliteal space is diamond-shaped; on its superior aspect it is bounded by the semimembranosus and semitendinosus muscles medially and by the biceps femoris muscle laterally. Its inferior boundaries are the two heads of the gastrocnemius muscle. The roof of the fossa is the thin popliteal fascia; the floor is the posterior aspect of the distal end of the femur, the posterior capsule of the joint, and the popliteus muscle, which overlies the proximal tibia.
- The popliteal artery and vein enter the popliteal space from its medial aspect through the adductor hiatus and lie directly behind the posterior capsule of the knee joint.
- They run obliquely through the fossa and branch into two superior, a single middle, and two inferior genicular branches. After exiting the popliteal fossa the popliteal artery divides into its terminal branches: the anterior tibial, posterior tibial, and peroneal arteries. The popliteal vein lies between the tibial nerve and the popliteal artery. The short saphenous vein pierces the popliteal fascia to join the popliteal vein within the fossa.
- The tibial nerve enters the popliteal fossa lateral to the popliteal artery and approximately in the middle of the fossa. It crosses the artery to its medial aspect and remains at that location. The common peroneal nerve slopes down the suprolateral border of the popliteal fossa toward the medial aspect and along the biceps femoris tendon, where it enters a tunnel within the substance of the peroneus longus muscle.

IMAGING AND OTHER STAGING STUDIES

Magnetic Resonance Imaging

- MRI is the imaging modality of choice for the diagnosis of popliteal soft tissue sarcomas. The typical finding is a soft tissue mass with a solid component, no communication to the knee, and central or irregular nodular gadolinium enhancement. Conversely, the classic presentation on MRI of popliteal cysts, which are the most frequently encountered masses in the popliteal fossa, is a well-defined, unilocular, fluid-filled cyst in direct communication with the knee joint; its peripheral walls are normally enhanced with gadolinium.
- MRI is also used to evaluate the size of the tumor and its relation to the neurovascular structures, the posterior knee joint capsule, and surrounding musculature and to assess local lymph node involvement (FIG 1A–C).

Plain Radiography and Computed Tomography

- Plain radiography and CT scans are performed to rule out invasion of the tumor into the adjacent bones.

Angiography

- Angiography (FIG 1D) is routinely used to assess the relation of the tumor to the popliteal artery, patterns of possible vascular displacement, the presence of vascular anomalies, and arterial and venous patency.

SURGICAL MANAGEMENT

Positioning

- The patient is placed in the prone position (FIG 2) and both lower limbs are draped. The contralateral leg is prepared for saphenous vein harvesting, which will be necessary for arterial reconstruction if the popliteal artery must be resected.
FIG 1 • MRI of a typical popliteal sarcoma. A. Normal MRI of the distal section of the popliteal (diamond) space through the medial and lateral gastrocnemius muscle insertions onto the femoral condyles. B. Large popliteal soft tissue sarcoma. C. Sagittal view showing the relationship of a popliteal sarcoma to the adjacent femur and knee joint (not involved in this case). D. Angiogram of an extremely vascular popliteal sarcoma. Arterial embolization may be useful. All of the small pedicles to the tumor must be ligated at the time of resection. The popliteal artery is rarely involved directly and is often preserved.

FIG 2 • Clinical photograph of a large popliteal sarcoma. A prone position is routinely used for surgical resection.

EXPOSURE

- An S-shaped incision is made, crossing from proximal-medial to distal-lateral at the level of the knee joint (TECH FIG 1A). The medial-proximal arm of the incision allows the popliteal vessels to be identified as they exit the adductor hiatus, and the lateral distal arm enables easy exposure of the peroneal nerve, posterior to the fibular head. In addition, making the distal arm of the incision lateral avoids damaging the greater saphenous vein, which runs on the medial aspect of the leg (TECH FIG 1B).
- The very thin and friable popliteal fascia lies in close proximity to the neurovascular bundle (especially the peroneal nerve, which lies just deep to the popliteal fascia at the level of the fibular head), making it a critical landmark. To identify the popliteal fascia, subcutaneous flaps are made. The landmarks and various structures of the popliteal fossa can often be palpated through the fascia, which is then cautiously incised accordingly. Failure to realize that the dissection is underneath the fascia and that only a few millimeters separates the blade from the vessels and nerves of the popliteal fossa can easily result in injury of those structures.
TECH FIG 1 • A. Incision used for resection of popliteal sarcomas. A wide exposure of the popliteal (diamond) space must be obtained to avoid inadvertent injury to important neurovascular structures. B. The medial and lateral hamstrings are mobilized and retracted with a wide self-retainer retractor. Similarly, the medial and lateral gastrocnemius heads are detached from the femoral condyles, retracted, or both. The two heads of the gastrocnemius muscles are split at the midline, taking care not to injure the now more superficial tibial nerve and vessels (located just anterior to the nerve).

TUMOR RESECTION

- The initial step of a popliteal fossa resection is exposure and identification of the neurovascular bundle. This allows the surgical team to mobilize the vulnerable structures before resection. Mobilization is usually accomplished by exposing the structures in the distal thigh and proximal leg and following them to the popliteal fossa (TECH FIG 2A,B). If the popliteal vessels are difficult to expose, an intraoperative Doppler ultrasound device can be helpful.
- After mobilizing the neurovascular bundle, the tumor is resected with a cuff of normal tissue if possible. Not uncommonly, however, the vessels, the nerves, or both are

TECH FIG 2 • A. The sciatic nerve is identified, as well as its two major branches, the tibial and peroneal nerves. B. Exposure and identification of the popliteal space and a large soft tissue sarcoma. The tumor has arisen between the sciatic nerve and the popliteal vessels. The nerve is easily seen and identified posteriorly and the popliteal vessels were found anterior to the tumor. (continued)
TECH FIG 2 • (continued) 

C. Lateral intraoperative view of the popliteal sarcoma. D. Surgical resection site after tumor removal. The sciatic nerves and the popliteal vessels were preserved.

In close proximity to the tumor mass or adherent to its pseudocapsule. In such cases, the structures are dissected free and the nerve sheath and adventitia are removed and pathologically examined using frozen sections to determine the surgical margins (TECH FIG 2C,D).

- Vessels and nerves of the popliteal fossa must be resected if they are embedded in the tumor mass. The popliteal artery can be reconstructed with a saphenous vein graft taken from the contralateral leg. We consider reconstructing the popliteal vein to be unnecessary because the ipsilateral saphenous vein can compensate for its loss. Nerve involvement or vascular involvement is not an indication for primary amputation if these features can be adequately resected.1,2,5

SOFT TISSUE RECONSTRUCTION

- After the tumor is resected, the two heads of the gastrocnemius are sutured to each other and to the hamstring muscles to form a uniform muscle layer that covers the popliteal space (TECH FIG 3A). This wound closure technique minimizes the occurrence of deep wound infection by forming a muscular barrier between the skin incision and the popliteal space. The resected tumor specimen is shown in (TECH FIG 3B,C).

TECH FIG 3 • A. Closure of popliteal space. The medial and lateral heads of the gastrocnemius muscles are tenodesed below the sciatic nerve to cover the popliteal vessels. The medial (semimembranosus muscle) and the lateral hamstrings (biceps femoris muscle) are similarly tenodesed proximally to close the popliteal space and are also tenodesed to the gastrocnemius repair. This closure closes off all the dead space as well as protecting the popliteal vessels and provides a nice muscle base if a skin graft is needed. B. Gross specimen of the popliteal sarcoma. C. The tumor transected.
PEARLS AND PITFALLS

- Soft tissue sarcomas of the popliteal fossa commonly displace the usual anatomic landmarks. To locate the components of the neurovascular bundle, one must expose regions that are proximal and distal to the popliteal fossa, identify the major nerves and vessels, and follow them to the popliteal fossa.

- The sciatic nerve is proximally identified between the medial and lateral hamstrings; distally, the peroneal nerve is carefully identified posterior to the fibular head, immediately below the thin popliteal fascia, and the tibial nerve is found between the two heads of the gastrocnemius.

- The popliteal vessels are identified proximal to the popliteal fossa as they exit the adductor hiatus and distally between the two heads of the gastrocnemius muscle. We routinely detach the origin of the medial and lateral hamstrings and both heads of the gastrocnemius muscle to achieve a wide exposure. In the popliteal space the nerves are usually found posterior to the tumor mass and the vessels are usually anterior to it.

- While running through the popliteal fossa the popliteal artery branches into two superior, a single middle, and two inferior genicular arteries. The inferior genicular vessels pull the popliteal artery toward the joint capsule and usually must be ligated to allow its mobilization. The popliteal vein, which runs more superficial to the artery, lies between the popliteal artery and the tibial nerve.

- The two main venous tracts responsible for the venous drainage of the leg are the popliteal vein and the greater saphenous vein. During tumor resection, excision of the popliteal vein may be unavoidable; for this reason, care should be taken not to damage the greater saphenous vein, which might be the only remaining venous tract. Moreover, if the popliteal artery and vein are resected, the contralateral greater saphenous vein should be harvested to reconstruct the popliteal artery. Ligation of both the popliteal vein and the ipsilateral greater saphenous vein may lead to severe venous insufficiency.

POSTOPERATIVE CARE AND REHABILITATION

- After surgery, the patient is placed in a long, posterior splint in 15 to 30 degrees of knee flexion to relieve tension from the neurovascular bundle and skin incision.

- Physiotherapy for muscle strengthening and range of motion is not started until the skin incision is completely healed.

OUTCOMES

- Only four case series of soft tissue sarcomas were identified in the English literature.3,7,8,10 All of the studies found that the prognosis was equivalent to that of soft tissue sarcomas in other locations and the limb salvage rate was high.

- In a recently published case series of 29 patients with popliteal sarcomas with a median postoperative follow-up of 79 months, of the 16 patients with high-grade tumors 3 (19%) had local recurrences and 4 (25%) had distant metastases; of these, 2 died.8 None of the patients with low-grade tumors had local recurrences or distant metastases. The overall limb salvage rate was 86.2%; for the patients with high-grade tumors it was 75%.8

COMPLICATIONS

- Superficial wound dehiscence is the most common complication. It usually occurs during adjuvant radiation therapy and sometimes necessitates local surgical débridement.

- Peroneal palsy is most commonly due to neuropraxia and usually resolves after several weeks.

- Knee range-of-motion limitation is usually secondary to adjuvant radiation therapy to the popliteal fossa. In our series of 29 patients with popliteal sarcomas, 14 of the 26 patients (53.8%) who underwent primary resections had full range of motion of the knee joint, 12 patients (46.1%) had mild to moderate limitations in knee flexion (120 to 90 degrees), and 4 patients (15.3%) had mild flexion contractures (5 to 15 degrees).8 No patient in our series required knee manipulation or contracture release.

REFERENCES

BACKGROUND

- Malignant tumors of the soleus and gastrocnemius muscles are rare and have been traditionally treated with above-knee amputation. During the past 20 years, the treatment of soft tissue sarcoma of the lower extremities has undergone a dramatic shift toward limb-salvage procedures.
- Better understanding of the biologic behavior of these tumors, the availability of effective neoadjuvant chemotherapy (which often decreases the tumor size and facilitates a more conservative resection), and the recognition that close negative surgical margins in conjunction with postoperative radiation therapy often provide good local control now allow tumor resection instead of amputation in most cases.

ANATOMY

- The soleus and gastrocnemius muscles form a tripartite muscle sometimes referred to as the triceps surae muscle. Together with the plantaris muscle they form the superficial posterior muscle group of the leg. These muscles act together in plantarflexing the foot and ankle joint.
- The gastrocnemius muscle is the most superficial in the superficial posterior compartment and forms most of the prominence of the calf. It has two heads of origin. Its medial head is slightly larger and extends a little more distal than its lateral head. The two heads converge at the inferior margins of the popliteal fossa, where they form the inferolateral and inferomedial boundaries. The lateral head originates from the lateral surface of the lateral femoral condyle and the medial head arises from the posterior surface of the femur, superior to the medial condyle.
- The soleus muscle is a broad fleshy muscle that lies deep to the gastrocnemius muscle. It arises from the posterior aspect of the head and superior fourth of the fibula, the soleal line, and the middle third of the medial border of the tibia. It also arises from the tendinous arch between the tibia and fibula, which arches over the tibial vessels. The soleus muscle and both heads of the gastrocnemius converge to form the Achilles tendon, which inserts into the posterior surface of the calcaneus.

INDICATIONS

- Tumors that arise from and are completely within the soleus muscle
- Most low-grade and some high-grade sarcomas

IMAGING AND OTHER STAGING STUDIES

Computed Tomography and Magnetic Resonance Imaging

- Careful examination of the CT and MRI is essential in determining resectability. Tumors that extend to and around the popliteal trifurcation or into the gastrocnemius muscles usually require an amputation (FIG 1).
- The popliteal space must also be evaluated. Proximal tumors arising within the soleus muscle often extend into the popliteal space and may involve the popliteal vessels, the sciatic nerve, or both.

Bone Scan

- Bone scans may show involvement of the adjacent tibia, fibula, or both.
- Areas of uptake should lead to close examination of the corresponding cuts of the MRI and CT scans.

Angiography and Other Studies

- Biplane angiography is very useful in determining vascular displacement or encasement.
- Careful analysis of the popliteal trifurcation is necessary before surgery and may indicate tumor involvement and thus the need for an amputation.

Biopsy

- The biopsy site should be in line with the planned incision for resection and must be located over the most prominent portion of the tumor.
- Core needle biopsy has been shown to provide reliable pathologic diagnoses and is our preferred method. Multiple samples can be collected from the same puncture site.
- Areas where major arteries and veins traverse should be avoided so as not to penetrate the vessels and risk tumor cell contamination.

SURGICAL MANAGEMENT

Positioning

- Resection is performed with the patient in a prone position. General or epidural anesthesia is used.
This patient with an alveolar soft part sarcoma of the soleus muscle was treated with induction chemotherapy followed by limb-salvage surgical resection and reconstruction with a Gore-Tex vascular graft. A, B. The axial and coronal T2-weighted MRIs show a large tumor arising within the soleus muscle. Arrows show the extension of the tumor.

**RESECTION OF SOLEUS MUSCLE WITH OR WITHOUT ADJACENT GASTROCNEMIUS MUSCLE**

- The initial incision is made longitudinally on the posterior aspect of the leg and shifted medially or laterally, depending on the anatomic location of tumor (TECH FIG 1A). A lateral incision is used if resection of the lateral gastrocnemius is planned. A midline posterior incision is used for resections of the medial gastrocnemius, soleus, and deep posterior compartment.
- The fascia is dissected with the subcutaneous tissues, and large fasciocutaneous flaps are raised. The peroneal nerve is first identified and placed within a vessel loop; this is followed by careful dissection to identify the sciatic and tibial nerves.
- The popliteal vessels are identified by opening up the deep fascia overlying the two heads of the gastrocnemius. Radical excision of the medial or lateral heads of the gastrocnemius is achieved by ligation of their main pedicle (medial or lateral sural artery and vein, respectively) and transection of their femoral origin and insertion to the Achilles tendon.
- Exposure for resection of the soleus muscle is achieved by partial or complete Achilles tenotomy and reflection of the medial and lateral heads of the gastrocnemius muscle proximally (TECH FIG 1B).
- By blunt dissection the soleus is separated from the transverse intermuscular septum, which outlines the deep posterior compartment (TECH FIG 1C, D). The soleus can then be detached from its tibial and fibular origins and calcaneal insertion.
- Residual defects in the Achilles tendon should be reconstructed. The wound is then closed over closed suction drains.

**TECH FIG 1** • A. Anatomy and a utilitarian approach to the posterior compartment of the leg. B. Exposure of the tumor and identification of the posterior vessels requires the release of the medial and lateral heads of the gastrocnemius muscle from the Achilles tendon. (continued)
Chapter 35  SOLEUS RESECTION

TECH FIG 1 • (continued)  C,D. Completion of tumor removal.  C. The massive defect created by wide resection of a soleus muscle sarcoma or carcinoma.  D. This intraoperative photograph shows the anatomic defect after tumor resection. The medial and lateral gastrocnemius muscles (MG, LG) were both mobilized and retracted proximally.

FUNCTIONAL RECONSTRUCTION AFTER RESECTION

- Functional reconstruction is usually necessary after resection of soleus tumors because of the complete resection of the proximal part of the Achilles tendon. It consists of tenodesing the medial and lateral heads of the gastrocnemius muscle and incorporating them with a Gore-Tex vascular graft. The length of the vascular graft depends on the size of the tumor and the gap between the resected stump and the Achilles tendon.
- The Gore-Tex vascular graft is sutured to the stump of the Achilles tendon with a 3-mm Dacron tape and #0 Ethibond sutures (TECH FIG 2A–D).
- The retracted gastrocnemius and soleus muscle stump is pulled out and sewn with the Gore-Tex aortic graft under moderate tension with a 3-mm Dacron tape and #0 Ethibond sutures.
- After resection of the tumor, the surgical specimen consists of the biopsy tract, the tumor, and the entire soleus muscle belly (TECH FIG 2E).
- The foot is kept in the neutral position during these reconstructive procedures. A posterior splint is used to maintain the foot in neutral position and the knee in 15 degrees of flexion.

TECH FIG 2 • A. The Gore-Tex vascular graft was sutured to the stump of Achilles tendon. Insert shows a close-up of the graft stump junction.  B. Suturing the medial and lateral heads of the gastrocnemius muscle and their incorporation with the Gore-Tex vascular graft.  C. This intraoperative photograph shows the anatomic defect reconstructed with the Gore-Tex vascular graft (arrows), which was anastomosed to the remaining gastrocnemius muscle (MG, LG) and the stump of the Achilles tendon (AT) with #0 Ethibond and 3-mm Dacron tape. (continued)
D. Postoperative MRI shows the Gore-Tex graft extending from the insertion of gastrocnemius muscle to the remaining stump of the Achilles tendon.

E. After tumor resection, the surgical specimen consists of the biopsy tract (BX), the tumor, and the entire soleus muscle belly (arrow).

NA — Not available.
PEARLS AND PITFALLS

Preoperative
- Large tumors of the soleus muscle may extend further than anticipated.
- Preoperative evaluation of the popliteal space and vessels is mandatory.

Intraoperative
- Reconstruction with a Gore-Tex graft after resection is recommended for large soleus defects.
- The surgeon should carefully mobilize the popliteal vessels before attempting to resect the tumor.
- An intraoperative Doppler scan may be useful.

POSTOPERATIVE CARE AND REHABILITATION
- Postoperatively, the leg is immobilized in a long-leg splint, followed by a short-leg walking cast for a total of 3 to 4 weeks, depending on the extent of the soft tissue resection.
- Patients who underwent reconstruction of the Achilles tendon with Gore-Tex graft should be immobilized in an ankle-foot orthosis for an additional 8 weeks.
- Rehabilitation includes leg strengthening, balance, and gait training (FIG 2).

OUTCOMES
- There have been only a few reported cases of soleus muscle resections for sarcomas. Reconstruction with a Gore-Tex graft allows the patient an almost normal gait (heel-toe, pushoff) and an almost normal range of motion of the ankle (Tables 1 and 2).
- Local recurrence may require an amputation.

COMPLICATIONS
- The most common complications are flap necrosis and tumor recurrence.
- Vascular occlusion of the posterior tibial artery is rare.
- Radiation therapy should be deferred a few weeks to permit the Gore-Tex graft to heal.

**Total score = (points for weight bearing) + (points for pain) + (points for functional capacity)**

**Interpretation:**
- Minimum total score: 0
- Maximum total score: 1000
- The higher the score, the more normal the function on the side with the ruptured tendon.
**BACKGROUND**

- Tumors of the sartorial canal are a unique group of tumors: they are extracompartmental space tumors with close proximity to the superficial femoral artery and vein.
- The sartorial canal, synonymous with the subsartorial canal, canal of Hunter, and femoral and adductor canal, runs from the femoral triangle proximally to the popliteal fossa on its distal end.
- Soft tissue sarcomas of the sartorial canal are rare, accounting for less than 2.5% of all soft tissue sarcomas.
- In the extremities, the distinction is made between intracompartmental and extracompartmental tumors because the two behave differently (Enneking stage Ia versus IIb).3,7 Tumors arising in the extracompartmental spaces may spread rapidly longitudinally far beyond their intracompartmental counterparts, and wide resection of these tumors is more demanding due to their proximity to major neurovascular structures.3,5,6
- Space tumors are a subgroup of tumors of the extracompartmental spaces. Such extracompartmental spaces are namely the sartorial canal, popliteal space, femoral triangle, and axilla.1-3
- A common assumption is that intracompartmental tumors are more amenable to control by local procedures (ie, easier to evaluate preoperatively and easier to resect surgically, with lower recurrence rates) compared with extracompartmental tumors.3 The only tumor factors proven to have a real prognostic effect are size, malignancy grade, depth, histotype, and local recurrence.4,7 Anatomic space or compartmental space has not been shown to have a significant prognostic impact. The surgical assumption is that treatment of space tumors is difficult, has more complications and a higher local recurrence rate, and may require primary amputation.

**ANATOMY**

- The canal lies between the anterior (quadriceps) compartment and the medial adductor compartment, connecting the tip of the femoral triangle in the proximal thigh to the popliteal space in the distal posterior aspect of the thigh. All three are considered “spaces” of the thigh, and each carries its own unique soft tissue tumors, presentation, treatment options, and hazards.
- Cross-section of the sartorial canal is shaped like an inverted triangle. The roof of the canal is the sartorius muscle, which lies anterior and medial to the canal. The adductor longus makes up the floor of the canal. The lateral border is the thick fascia of the vastus medialis. Posteriorly the border of the canal is the adductor compartment, namely the adductor magnus. Both the posterior and lateral borders are covered with thick fascia. The superficial femoral artery and the femoral vein enter the canal through the tip of the femoral triangle. These structures lie deep in the canal, where they are surrounded throughout its length with very thick fascial sheath. The vessels exit the canal at the distal medial end, through the adductor hiatus, a foramen in the distal part of the adductor magnus.

**INDICATIONS**

- Tumors of the sartorial canal are often malignant and should all be removed as soon as possible. Tumors of the canal are all deep tumors that are in intimate proximity with the main vessels to the lower limb. Small tumors are as suspicious as large tumors because they may be high-grade tumors about to invade the vessels. Early resection avoids vessel involvement and thus lessens the need for arterial resection and reconstruction and most likely lowers the risk of metastatic disease with high-grade tumors. Tumors of the sartorial canal should not undergo core needle biopsy but rather excisional biopsy with frozen section during surgery.
- Patients present initially with a painless mass in the medial thigh. Some of the masses may be larger than 20 cm and may have been growing slowly for years. There is no clear correlation between the size of the tumor at presentation and its malignancy.

**IMAGING AND OTHER STAGING STUDIES**

**Plain Radiography**

Plain radiography studies are performed to rule out local invasion of the femur by the tumor and to rule out soft tissue calcifications (pathognomonic of synovial sarcoma and hemangiomas).

**Computed Tomography and Magnetic Resonance Imaging**

- CT with 3D reconstruction and arterial contrast has been used to assess the anatomic relation between the main vessels of the limb and the tumor. Due to the small space in the canal and the proximity to the vessels, tumors distort the normal anatomy early in their growth and may displace the vessels. Therefore, good imaging is crucial.
- MRI is used to assess the tumor’s anatomic relation to the vessels and to evaluate the tumor’s size and invasion of neighboring anatomic structures, namely the muscles bordering the canal and the proximal and distal extent, the femoral triangle, and popliteal spaces (FIGS 1, 2A).
- MRI often identifies the specific structure from which the tumor arises and invades the canal (sartorius, vastus medialis, and adductor muscles).

**Bone Scan**

Bone scan is used to rule out distant metastatic disease and may give a clue about the malignancy of the tumor: high-grade tumors show a strong tumor blush in the late arterial flow phase of the three-phase technetium bone scan.
Angiography and Other Studies
- Angiography is used to assess the vascularity of the tumor, tumor blush, the location of the vessels feeding it, and the relation between the tumor and the femoral artery, which indicates whether the vessel was displaced by the tumor or is invading the vessels (FIG 2B).
- Venography of the limb is used to rule out venous thrombus, tumor thrombus (mural thrombus), or direct tumor involvement.

Biopsy
- Core needle biopsy and open incisional biopsy are problematic in the sartorial canal. Therefore, biopsy should be done using frozen section at the time of definitive surgery. Most tumors within the sartorial canal are malignant, so all should be removed. The risk of a biopsy with either an inaccurate diagnosis or local contamination warrants the consideration of primary resection.
- The proximity of the tumor to the vessels carries several disadvantages when considering biopsy:
  - Hematoma from the biopsy site may spread along the vessels, thus contaminating the extremity and necessitating an amputation.

SURGICAL MANAGEMENT
- Tumors such as leiomyosarcomas may arise from the vessel walls; therefore, the main vessels may be punctured at the time of biopsy, causing significant bleeding.

FIG 1 • Axial (A) and sagittal (B) MR image of a sartorial canal tumor that approximates the vessels. The tumor is a low-grade liposarcoma. SF A&V, superficial artery and vein.

FIG 2 • A. Axial MR image of a tumor of the sartorial canal that arises from the muscle wall and encroaches on the vessels. B. Angiogram of the same lesion showing tumor blush from the late arterial phase.
wide exposure. Proximal and distal control of the vessels should be achieved before beginning to resect the tumor.

- There are two main venous tracts that drain blood from the limb, the popliteal vein and the greater saphenous vein. Care must be taken not to damage the saphenous vein because resection of the femoral vein may be unavoidable due to tumor invasion. Ligation of both veins would lead to severe venous insufficiency of the limb.

- A thick fascial sheath covers the superficial femoral artery and vein throughout its length. This fascia often separates the tumor from these major vessels and provides a safe plane of dissection. This fascia is routinely analyzed under frozen section during surgery to confirm the adequacy of resection. In these extracompartmental resections, achieving 1 cm of normal tissue borders is often not possible. Sarcomas are known to respect fascial boundaries; therefore, dissecting an intact adventitia off the vessels that is free of tumor on pathologic inspection should provide sufficient resection margins.

Preoperative Planning

- Tumors of the sartorial canal may be divided according to their anatomic and surgical location into three types of resections. This classification is designed to serve as a guideline for the surgeon. By analyzing preoperative imaging and the initial intraoperative surgical impression, the surgeon can assess the structures from which the tumor arises and the appropriate plane of resection. These guidelines correlate with the surgical margins and, in general, the higher the number the more difficult the surgical resection and reconstruction will be.

- Tumors are classified according to the location from which they originate (FIG 3):
  - Type 1 (luminal) tumors arise from within the space. Typically they originate from fat or fibrous tissue within the space and lie loose in the space. We call these tumors “luminal” because they may approximate but are not adherent to the walls of the space or any of the arteries, veins, and nerves in the sartorial canal.

---

FIG 3 • Systematic resection of extracompartmental space tumors of the sartorial canal. The left column shows axial MR images of the three different types of tumors in the sartorial canal. The middle column shows a schematic of the tumor location and the right column shows the recommended planes of surgical resection (dotted line). Resection types from 1 to 3 are presented in the rows from top to bottom. Type 1 (luminal) tumors lie within the space and are resected with a thin cuff of tissue that surrounds them. Type 2 (wall) tumors arise from the muscles surrounding the space and are resected as a typical muscle resection. Type 3 (vessel) tumors invade the vessels and are therefore resected en bloc with the vessels.
- Type 2 (wall) tumors arise from one of the walls that border the sartorial canal (sartorius, vastus medialis, adductor magnus or adductor longus muscles). These tumors arise from within a muscle or the muscle’s fascia that borders the space.
- Type 3 (vessel) tumors involve arteries, veins, or nerves. These lesions originate from the vessel wall and are not simply juxtaposed to it.
- Tumors are classified into one of these three types according to the preoperative imaging and the surgeon’s intraoperative impression. Each type of tumor should be resected with different plane of resection:
  - Type 1 tumors are resected with a thin layer of normal tissue that abuts the tumor. This normal tissue is typically the thick encasing fascia over the vessel. Vascular resection is not required. At times these tumors almost deliver themselves once the space is opened. Tumor margins, although negative, are often close. The fibrous sheath surrounding the vessels is inspected by carefully resecting it and examining the sheath on frozen section to rule out tumor invasion.
  - Type 2 tumors are essentially resected with the muscle from which they originate. Wide surgical resection is achieved by resecting the tumor with a large cuff of muscle of origin, the fascia covering that muscle, and adjacent fat from within the canal.
  - For type 3 tumors, there is no safe way to resect the lesion and guarantee negative margins without resecting the vessel itself. The vessel and the lesion must be resected en bloc with adjacent muscle or fascia as required. If the artery is resected it must be reconstructed with a synthetic graft or a reverse saphenous vein graft. Venous resections do not need reconstruction as long as the ipsilateral saphenous vein is intact. Because the tumor is resected en bloc with the vessel, these resections, although challenging surgically in their reconstructive aspects, are relatively simple in their tumor resection aspects and in achieving wide surgical margins.

**Positioning**

- The patient is placed in the supine position and the leg is prepared and draped. The contralateral leg should be prepared and draped as well in case a saphenous vein graft is needed for vascular reconstruction.

**Approach**

- The skin incision is made along the sartorius muscle throughout its length as necessary. Fasciocutaneous flaps are raised anteriorly and posteriorly for wide exposure (FIG 4).
- The sartorius muscle is disconnected at its distal end and the inferior border of the muscle is retracted anteriorly. The canal is carefully dissected open.
- At this point it is important to identify and control the major vessels at both ends of the canal, near the adductor hiatus and the femoral triangle. Small perforating vessels connecting the tumor to the main vessels are ligated.
- The surgical classification for tumors of anatomic spaces helps dictate the type of resection needed for each type of tumor.

**FIG 4** - Surgical approach to resecting a tumor of the sartorial canal. Skin incision is carried along the sartorius muscle. Fasciocutaneous flaps are raised anteriorly and posteriorly for wide exposure. The sartorius muscle is either resected with the tumor if necessary from an oncologic point of view or disconnected distally for wide exposure. The adductor hiatus is opened to better expose the vessels as they pass from the canal into the popliteal space (inset).
**Techniques**

- The femoral vein may be sacrificed if the tumor is in intimate contact with it. If the saphenous vein is intact, there is no need to reconstruct the femoral vein.
- The wound is marked with hemoclips for postoperative radiation therapy.
- After tumor resection, the femoral vessels are covered with muscle flaps comprising either the sartorius muscle or, if that was excised with the tumor, the adjacent gracilis muscle. A gracilis muscle transfer (TECH FIG 1C) is done by dissecting the distal end of the gracilis free and rotating the muscle anteriorly to cover the canal. This provides good soft tissue coverage.

**Pearls and Pitfalls**

| Tumor may involve the vessels and necessitate resection of vessels. | **A vascular surgeon should be on call for reconstruction if needed.** |
| Loss of both the femoral and saphenous vein in the same leg will cause symptomatic edema. | **Injury to the saphenous vein is avoided during dissection, as the femoral vein may have to be resected due to tumor involvement.** |
| **If both veins are nonfunctional, the femoral vein is reconstructed with a saphenous vein graft.** | **The soft tissue of the canal is reconstructed with sartorius remnants and a gracilis muscle transfer.** |
| **Cover vessels with muscle to protect them in case of postsurgical superficial wound infection or wound dehiscence after radiation.** |  |

**Postoperative Care**

- Physiotherapy for full range of motion of the hip and knee joint may commence as soon as the wound has healed and skin sutures have been removed. Full weight bearing is permitted after surgery.
- Leg edema should be monitored after venous resection. The leg should be kept elevated.
- Radiation therapy may be started as soon as the wound has healed; this is typically no sooner than 3 weeks after surgery. In patients with arterial graft reconstruction, we believe it is safe to begin radiation therapy 3 weeks after surgery.

**Outcomes**

- Functional outcome is excellent. Because the surgical resection and postoperative radiation do not cross a joint line, there is no restriction in range of motion.

**Complications**

- Complications of tumor surgery in the sartorial canal occur mainly when there is involvement of the vessels and reconstruction. These complications include deep infection, arterial occlusion, and deep vein thrombosis.

**References**

BACKGROUND

- The femur is the most common site for metastatic bone disease requiring surgery. Because it is a major weight-bearing bone with minimal space for surgical errors, the operative procedure must be carefully planned and meticulously executed, with the aim of achieving durable reconstruction. Detailed preoperative clinical and imaging evaluation is essential to define the morphologic characteristics of the lesion that validate surgical intervention and to distinguish between lesions that can be managed with curettage and cemented fixation and those that require resection with endoprosthetic reconstruction.\(^1,6,7\)

- Unlike primary sarcomas of the femur, metastatic tumors usually have a small soft tissue component, even in the presence of extensive bone destruction. This feature allows the sparing of extracortical structures, such as the joint capsule, overlying muscles, and muscle attachments, and the possibility of applying them for reconstruction and preservation of function.

- Because of distinctive differences in anatomic and surgical considerations, surgeries around the proximal femur, femoral diaphysis, and distal femur will be discussed separately (FIG 1).

ANATOMY

Proximal Femur

- A thick joint capsule encircles the femoral head and neck and attaches to the base of the neck.
- Key elements at the lateral aspect: The greater trochanter is the insertion site for the gluteus medius muscle (lateral stabilizer and hip abductor) and the origin for the vastus lateralis muscle.
- Key elements at the medial aspect: The minor trochanter is the insertion site for the psoas muscle (medial stabilizer and hip flexor).

Femoral Diaphysis

- The femoral diaphysis is encircled by two muscle layers:
  - First layer: the vastus intermedius muscle
  - Second layer: The rectus femoris and vastus medialis muscles intersect at the anteromedial aspect, and the rectus femoris and the vastus lateralis muscles intersect at the anterolateral aspect.

Distal Femur

- The medial femoral condyle is positioned below the insertion site of the vastus medialis muscle.
- The lateral femoral condyle is positioned below the insertion site of the vastus lateralis muscle.

INDICATIONS

- Pathologic fracture
- Impending pathologic fracture (FIG 2)

FIG 1 • Metastatic tumors at the proximal femur, femoral diaphysis, and distal femur.

FIG 2 • AP and lateral plain radiographs showing an impending fracture of the femoral diaphysis due to metastatic lesions.
Intractable pain associated with locally progressive disease that has shown inadequate response to narcotics and radiation therapy

Solitary bone metastasis in selected patients and tumor types (eg, those with breast cancer and renal cell carcinoma)

**IMAGING AND OTHER STAGING STUDIES**

Plain radiographs of the entire femur are mandatory to rule out coexisting metastases that may influence the extent and technique of surgery. CT of the lesion will clearly define the extents of soft-tissue component and bone destruction. Total body bone scintigraphy is done to detect coexisting metastases elsewhere in the skeleton (FIG 3). The results of imaging should provide the surgeon with answers to the following questions:

- Is the lesion an impending fracture? (If not, it should probably be treated nonoperatively).
- Are there additional femoral metastases? If so, can they be managed by nonoperative techniques or do they also require surgery?
- What is the appropriate surgical approach? As a rule, tumor curettage with cemented fixation is indicated for lesions in which the remaining cortices allow containment of the fixation device. Otherwise, surgery consists of resection of the affected bone segment with prosthetic reconstruction.

![FIG 3](image-url)

A. Plain radiograph showing a metastatic lesion of the proximal femur. The surrounding cortices are intact. Surgery consisted of curettage and reconstruction with a cemented intramedullary nail.

B. Metastatic lesion at the same site with extensive circumferential bone destruction. Surgery in this case entailed resection of the proximal femur and reconstruction with an endoprosthesis.

C. AP plain radiograph (C) and computed tomography (D) of the distal femur showing a metastatic lesion at the left medial femoral condyle. The lateral condyle and articular cartilage are preserved and form an anatomic continuum, which allows the fixation of a cemented reconstructive device.

D. AP (E) and lateral (F) plain radiographs and computed tomography (G) of the distal femur showing a large metastasis with destruction of the entire anterior aspect of the bone and considerable thinning of the posterior cortex. Surgery included resection of the distal femur and reconstruction with an endoprosthesis.
PROXIMAL FEMUR

Position and Incision

- The patient is placed supine on the operating table, with the buttock of the affected side close to its edge. The operating table is positioned in a 30-degree tilt away from the surgeon.

  - A straight longitudinal incision is made along the tip of the greater trochanter and femoral diaphysis (TECH FIG 1). It should begin 5 cm proximal to the greater trochanter to allow the introduction of a femoral nail and 5 cm below the lower edge of the lesion to enable adequate tumor curettage.

Exposure

- The fascia lata is divided longitudinally and retracted to expose the lower edge of the gluteus medius muscle and its insertion site at the greater trochanter muscle, the vastus ridge, and the upper part of the vastus lateralis muscle (TECH FIG 2A,B).

  - Using electrocautery, the vastus lateralis muscle is detached from the vastus ridge and the lower aspect of the proximal diaphysis and reflected anteriorly to expose the diaphyseal cortex (TECH FIG 2C–E). A longitudinal cortical window with oval edges is made below the vastus ridge (TECH FIG 2F).

Tumor Removal

- Gross tumor is removed with hand curettes (TECH FIG 3A,B). Curettage should be meticulous and should leave only microscopic disease in the tumor cavity. It is followed by high-speed burr drilling of walls of the tumor cavity (TECH FIG 3C,D).

TECH FIG 1 • A straight longitudinal incision is made along the tip of the greater trochanter and femoral diaphysis.

TECH FIG 2 • A,B. The fascia lata is divided longitudinally and retracted to expose the lower edge of the gluteus medius muscle and its insertion site at the greater trochanter muscle, the vastus ridge, and the upper part of the vastus lateralis muscle. C–E. The vastus lateralis muscle is detached from the vastus ridge and femoral diaphysis. (continued)
TECH FIG 2 • (continued) F. A cortical window is made below the vastus ridge.

TECH FIG 3 • A,B. Gross tumor is removed with hand curettes. C,D. Curettage is followed by high-speed burr drilling of the walls of the tumor cavity. E. The gluteus medius muscle is detatched and reflected from its insertion site at the greater trochanter muscle. (continued)
When a proximal femur resection is done, the gluteus medius muscle is detached and reflected from its insertion site at the greater trochanter muscle (TECH FIG 3E), the joint capsule is opened and the femoral head is dislocated from the acetabulum, the medial aspect of the proximal femur is freed of muscle attachments, and then an osteotomy is performed below the lower aspect of the tumor (TECH FIG 3F–H).

**Mechanical Reconstruction**

Reconstruction begins with the introduction of an intramedullary nail. After proper positioning and length are verified, the nail is partially withdrawn and the entire tumor cavity is filled with cement (TECH FIG 4A). The nail is then pushed back into the medullary canal and fixed with interlocking screws (TECH FIG 4B,C). Alternatively, a side plate and a sliding screw can be sim-
Chapter 37  SURGICAL MANAGEMENT OF METASTATIC BONE DISEASE: FEMORAL LESIONS

TECHNIQUES

TECH FIG 4D  Similarly used for reconstruction. After resection of the proximal femur, a cemented tumor prosthesis is used to reconstruct the bone defect.

Soft Tissue Reconstruction and Wound Closure

- The origin of the vastus lateralis muscle is reattached to the vastus ridge (TECH FIG 5A). If endoprosthetic reconstruction had been carried out, the remaining hip capsule is sutured tightly with a 3-mm Dacron tape around the neck of the prosthesis, forming a noose that provides immediate stability. The capsule is reinforced by rotating the external rotator muscles proximally and suturing them to its posterolateral aspect. The remaining abductor tendon is attached to the lateral aspect of the prosthesis through a metal loop, and the psoas muscle is attached to the medial aspect of the prosthesis at the level where the lesser trochanter had been (TECH FIG 5B).
- It is important to attach these two muscles to the prosthesis so that balanced function will be achieved. The surgical wound is then closed over suction drains and the patient is placed in balanced suspension or in tibial pin traction with the hip elevated and flexed 20 degrees. An abduction pillow can also achieve the correct positioning.

Postoperative Care

- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. If tumor curettage had been done, rehabilitation should include early ambulation with unrestricted weight bearing as well as passive and active range of motion of the hip joint.
- After wound healing, usually 3 to 4 weeks after surgery, the patient is referred for adjuvant radiation therapy. Adjuvant radiation therapy is usually not required in patients who underwent proximal femur resection with endoprosthetic reconstruction.
- If endoprosthetic reconstruction had been done, the extremity is kept in balanced suspension for at least 5 days. Postoperative mobilization with total hip replacement precautions with or without an abduction brace and weight bearing as tolerated are continued for 6 weeks.

FEMORAL DIAPHYSIS

Position and Incision

- The patient is placed supine on the operating table, with the buttock of the affected side close to its edge. The operating table is positioned in a 30-degree tilt away from the surgeon.
- A diaphyseal lesion with a lateral cortical breakthrough is approached using a longitudinal incision along the anterolateral aspect of the thigh at the level of the interface between the rectus femoris and vastus lateralis muscles, with the lesion located at the center of the incision.
- A lesion with medial cortical destruction is similarly approached using an anteromedial incision at the level of the interface of the rectus femoris and vastus medialis.
Exposure
- The interval between the rectus femoris and vastus lateralis muscles is opened, and the muscles are retracted to expose the vastus intermedius overlying the femoral diaphysis. The vastus intermedius is split longitudinally to expose the femoral diaphysis, and retractors are placed behind it (TECH FIG 6). This approach allows wide exposure of the affected bone with minimal injury to the overlying muscles. A longitudinal cortical window with oval edges is made above the lesion.

Tumor Removal
- Gross tumor is removed with hand curettes (TECH FIG 7A,B). Curettage should be meticulous and should leave only microscopic disease in the tumor cavity. This is followed by high-speed burr drilling of the walls of the tumor cavity (TECH FIG 7C,D).

Mechanical Reconstruction
- Reconstruction begins with the introduction of an intramedullary nail either antegrade or retrograde, depending on the location of the lesion along the diaphysis. After proper positioning and length have been verified, the nail is partially withdrawn and the entire tumor cavity is filled with cement (TECH FIG 8). The nail is then pushed back into the medullary canal and fixed with interlocking screws.

Soft Tissue Reconstruction and Wound Closure
- A suction drain is positioned along the femoral diaphysis muscle, and the vastus lateralis muscle is sutured to the rectus femoris muscle.
Chapter 37  SURGICAL MANAGEMENT OF METASTATIC BONE DISEASE: FEMORAL LESIONS

TECH FIG 8 • An intramedullary nail is introduced and adequate positioning is verified. The nail is then partially withdrawn, the tumor cavity is entirely filled with cement, and the nail is reintroduced through the cement and secured with interlocking screws.

Postoperative Care

- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. Rehabilitation should include early ambulation with unrestricted weight bearing as well as passive and active range of motion of the knee joint.
- When wound healing is complete, usually 3 to 4 weeks after surgery, the patient is referred for adjuvant radiation therapy.

DISTAL FEMUR

Position and Incision

- The patient is placed supine on the operating table, with the affected knee flexed 30 degrees.
- A medial condyle lesion is approached using a longitudinal incision along the anteromedial aspect of the distal thigh at the level of the interface between the rectus femoris and vastus medialis muscles and 1 cm away from the medial border of the patella (TECH FIG 9).
- A lesion of the lateral condyle is similarly approached using an anterolateral incision at the level of the interface of the rectus femoris and the vastus lateralis and lateral to the patella.

Exposure

- The interval between the distal aspect of the vastus medialis and rectus femoris muscles is opened and the insertion of the vastus medialis to the quadriceps tendon, patella, and joint capsule is detached (TECH FIG 10A,B). The vastus medialis muscle is retracted posteriorly, exposing the underlying vastus intermedius muscle and the distal femur (TECH FIG 10C,D).

Tumor Removal

- A lesion at the lateral femoral condyle is approached using similar detachment and posterior reflection of the vastus lateralis muscle. This approach allows wide exposure of the affected bone with minimal injury to the overlying muscles. A longitudinal cortical window with oval edges is made above the lesion.
- Curettage. Gross tumor is removed with hand curettes (TECH FIG 11A,B). Curettage should be meticulous and should leave only microscopic disease in the tumor cavity. It is followed by high-speed burr drilling of walls of the tumor cavity (TECH FIG 11C,D).
- Distal femoral resection (see Chap. ON-25). TECH FIG 11E,F show the release of the vastus medialis and the popliteal exposure. TECH FIG 11G,H show the release of all soft tissues around the distal femur and the femoral osteotomy. The cavity is reconstructed by a combination of intramedullary and plate fixation followed by cement (PMMA). See TECH FIG 12A.
TECH FIG 10 • A,B. The vastus medialis muscle is detached from its attachment to the rectus femoris muscle and inserted into the quadriceps tendon, patella, and joint capsule. C,D. The vastus medialis muscle is retracted posteriorly, exposing the vastus intermedius muscle and distal femur.

TECH FIG 11 • A,B. Gross tumor is removed with hand curettes. (continued)
Tech Fig 11 (continued) C, D. Curettage is followed by high-speed burr drilling of the walls of the tumor cavity. E, F. The medial gastrocnemius muscle is detached and reflected, exposing the popliteal fossa. The posterior femur is isolated by ligation and transection of the geniculate vessels. G. The joint capsule is opened and released circumferentially from the femur. H. A distal femur osteotomy is done 1 to 2 cm beyond the point of proximal tumor extension.
A distal femur osteotomy is carried out at the appropriate location as determined by the preoperative imaging studies: 1 to 2 cm beyond the point of proximal tumor extension is generally appropriate for metastatic tumors (TECH FIG 11H–J). A tibial osteotomy is then done to allow the introduction of the prosthetic tibial component.

### Mechanical Reconstruction
- A combination of a cemented intramedullary nail and a condylar plate achieves optimal stability and is preferred for reconstruction (TECH FIG 12A–C). After resection of the distal femur, a cemented tumor prosthesis is used for reconstruction (TECH FIG 12D–F).

### Soft Tissue Reconstruction and Wound Closure
- Suction drains are positioned along the femoral diaphysis, and the vastus medialis muscle is sutured to the rectus femoris muscle and its insertion sites along the quadriceps and patella. The medial gastrocnemius muscle is pulled up and sutured to the vastus medialis muscle (TECH FIG 13).

### Postoperative Care and Rehabilitation
- Continuous suction is required for 3 to 5 days, and perioperative intravenous antibiotics are continued until the drainage tubes are removed. If tumor curettage had been done, rehabilitation should include early
ambulation with unrestricted weight bearing as well as passive and active range of motion of the knee joint.

When the wound is healed, usually 3 to 4 weeks after surgery, the patient is referred for adjuvant radiation therapy. In the case of distal femur resection, the lower extremity is elevated for 3 days, until the first postoperative wound check, to prevent wound edema. Knee motion is restricted in an immobilizing brace for 2 to 3 weeks to allow healing of the surgical flaps and until the extensor mechanism is again functional. During that time, isometric exercises are carried out and weight bearing is allowed. Adjuvant radiation therapy is usually not required in patients who underwent distal femur resection with endoprosthetic reconstruction.

PEARLS AND PITFALLS

Proximal femur
- Adequate imaging of the entire femur: allows the surgeon to decide whether to perform tumor curettage or resection with endoprosthetic reconstruction
- Wide exposure of the tumor cavity, using an adequately positioned and large cortical window
- Meticulous curettage and burr drilling
- Reconstruction with hardware and cementation of the entire volume of the cavity
- Proximal femur resection: reconstruction with cemented implant, suturing of the joint capsule, and reattachment of the gluteus medius and psoas muscles
- Early ambulation and range-of-motion exercises; weight bearing as tolerated

Femoral diaphysis
- Exposure through the interval between the rectus femoris and vastus lateralis or medialis
- Wide exposure of the tumor cavity using an adequately positioned large cortical window
- Meticulous curettage and burr drilling
- Reconstruction with hardware and cementation of the entire volume of the cavity
- Early ambulation and range-of-motion exercises; weight bearing as tolerated

Distal femur
- Intraoperative
  - Exposure through the interval between the vastus medialis and lateralis and the rectus femoris
  - Wide exposure of the tumor cavity using an adequately positioned large cortical window
  - Meticulous curettage and burr drilling
  - Reconstruction with a cemented intramedullary nail and a condylar plate
  - When distal femur resection is indicated, the gastrocnemius origin is detached to expose the popliteal fossa.
  - Reconstruction is done with a cemented tumor prosthesis.

- Postoperative
  - Early ambulation and weight bearing as tolerated
OUTCOMES AND COMPLICATIONS

- Functional outcomes and common complications of prosthetic replacements for metastatic bone disease are no different from those with the same operations for primary sarcomas of bone (see Chaps. ON-25 and ON-26). 2–5,8 Because of the short life expectancy of most patients with metastatic bone disease, however, the problems seen at long-term follow-up, such as aseptic loosening, the wearing down of polyethylene components, and fatigue prosthetic fractures, are rarely seen.

- The real concerns in the setting of metastatic bone disease are local tumor recurrence and failure of reconstruction. Meticulous tumor removal, proper selection and use of fixation devices, and adjuvant radiation therapy have made these complications rare: local recurrence and reconstruction failures are seen in less than 5% of the patients.

REFERENCES

BACKGROUND

- Malignant tumors of the foot present a significant and formidable challenge to the orthopaedic oncologist due to the foot’s unique function and anatomic peculiarities.
- The foot is uniquely adapted for bipedal motion and as such is essentially a tripod. The tripod is basically formed by the first ray, the fifth ray, and the calcaneus and is supported by the osseous configuration of bones in the midfoot that form a Roman arch, which in and of itself is inherently stable.
- Both bone and soft tissue contribute to the structure and function of the foot. Furthermore, the foot is composed of compact compartments that are interconnected by nerves and vascular structures. Complete resection (wide local excision) of osseous structures of the foot is difficult because of the interruption of these complex anatomic relationships, which afford stability to the foot, in addition to the interconnected compartments. Malignant tumors of bone are rare in the foot and rarer still in locations distal to the metatarsophalangeal joints.
- Many of these tumors are treated with amputations.
- In the senior author’s experience of 153 foot and ankle tumors in 153 cases, 31 amputations were performed (FIG 1A). Fortunately, tumors distal to the metatarsophalangeal joint can be treated by amputation through the metatarsophalangeal joint with minimal disruption to function. The only exception is the first ray, which typically bears 50% of the weight with toe-off during each gait cycle. Therefore, preservation of as much proximal phalanx as possible is important to optimize this important structure.

INDICATIONS

- Tumors involving the toe or metatarsal bone are rare. Primary tumors affecting the foot, including osteosarcomas, have a low incidence. Metastatic tumors of the foot are also rare. The most common sites of primary tumors are lung, kidney, and colon.
- In the senior author’s experience of 153 foot and ankle tumors, 73 cases were bony (FIG 1B); of these, 7 cases involved the metatarsals (FIG 1C). The indications for ray resections are tumors involving the toe or metatarsal bone. Benign tumors make up the majority of these lesions.
- **FIGURE 1D** shows the distribution of benign versus malignant diagnoses. The malignant lesions include metastatic disease, primary bony tumors, and soft tissue tumors.

ANATOMY

- The tripod is basically formed by the first ray, the fifth ray, and the calcaneus and is supported by the osseous configuration of bones in the midfoot that forms a Roman arch, which in and of itself is inherently stable.
- These bones are supported by ligamentous structures as well as tendons that help preserve the arch and support foot function. For this reason, resections of the first and fifth rays typically result in significant alterations in function, especially the first ray. The resulting forces after resection of the first ray result in transfer to the lesser metatarsals, which are ill adapted to structurally support the weight of the body, resulting in transverse metatarsalgia.
- These structural alterations can be mitigated in part by the judicious use of orthotics, such as a medial heel wedge to transfer the forces farther lateral or the use of a metatarsal bar, which will more evenly distribute the weight across the lesser metatarsals. Resection of the fifth ray is relatively easily compensated for by creating an orthosis that transfers the forces medially; thus, a lateral heel wedge is beneficial.
- Resection of the middle rays results in insignificant loss of function and acceptable cosmesis. The only net result is narrowing of the forefoot, which can be easily compensated for with shoe modifications.

PATIENT HISTORY AND PHYSICAL FINDINGS

- Patients with tumors of the toe or metatarsal present with pain and mass. The mass may be small and chronic. It may appear with an injury.
- Physical examination (Table 1) will reveal a tender mass localized to the toe or metatarsal. There may be associated swelling. If a sensory nerve overlies the mass, there may be paresthesia.

IMAGING AND OTHER STAGING STUDIES

- Preoperative studies include plain radiographs of the foot, including anteroposterior, lateral, and oblique views. If the ankle joint is involved, then anteroposterior and mortise views are obtained.
- MRI is important to evaluate the amount of involvement of the metatarsals to determine the level of amputation. The case in **FIGURE 2** shows cortical thickening of the second metatarsal. The clinical photographs show increased space between the metatarsals. MRI shows the soft tissue involvement. The lesion was found to be benign.

SURGICAL MANAGEMENT

- The goal of the surgical procedure is to remove the tumor with adequate margins.
- A long plantar flap is important for a sturdy end-bearing stump.
- The bony edges should be smooth and beveled if possible.
- Myodesis is helpful to pad the end of the stump.
- **Figure 2** shows pigmented villonodular synovitis (PVNS) localized to the plantar aspect of the first metatarsal head. The clinical photographs show the mass. MRI shows the soft tissue involvement. Intraoperative photograph shows resection of the tumor.
FIG 1 • A. Distribution of types of amputations for 153 tumors of the foot and ankle (n = 31). B. All diagnoses of bony tumors of the foot and ankle (n = 73). C. Diagnoses of metatarsal tumors (n = 7). D. Distribution of bony tumors of the foot and ankle by diagnosis and site (n = 73).

Preoperative Planning

- Preoperative planning is crucial for a good outcome. The preoperative radiographs and CT and MRI studies are important to determine the amount of tumor involvement. They also show the extent of soft tissue tumors and may be helpful in distinguishing benign from malignant tumors. The biopsy results will determine the level of amputation.
- The level of amputation is an important part of preoperative planning. The length of the residual stump is as important as the quality of soft tissue. There must be adequate padding of skin, subcutaneous fat, muscle, and tendons to cover the end of the bones.

Positioning

- The patient is placed supine on the operating table. A thigh tourniquet is placed over adequate cotton padding. A bump may be placed proximal to the sciatic notch on the ipsilateral hip to limit external rotation of the extremity during the procedure.

Approach

- The surgical approach is planned preoperatively. It is important to maintain as much plantar skin as possible because this skin is thicker and has specialized columns of plantar fat for weight bearing.
RAY RESECTION

- In performing a ray resection, an incision is made longitudinally and dorsally in line with the involved metatarsal (TECH FIG 1A,B). At the metatarsophalangeal joint, the incision is carried plantarly in a curvilinear fashion around the joint. This tissue is then used to reconstruct the resulting web space between the adjacent digits.
- The sensory nerves are identified just beneath the skin and are pulled distally and transected sharply with a scalpel. The extensor tendon is also transected sharply at and proximally near the tarsometatarsal joint.
- The common digital nerve is identified along with the vascular bundle. If they are involved or closely adherent to the tumor pseudocapsule, they are ligated proximally. The lumbrical and interosseous muscles are transected proximally, exposing the base of the metatarsal. It is preferable to preserve the base of the metatarsal if possible because this does not cause any disruption in the arch formed by the tarsal–metatarsal articulation.
- An oscillating saw is used to transect the metatarsal, or the metatarsal is disarticulated at the tarsometatarsal joint and elevated. The resection then is performed from proximal to distal. The flexor tendon is identified and transected. The entire metatarsal is then excised along with the adjacent soft tissue (lumbricals, intrinsics, and flexor extensor tendons). The dissection is then carried distally and plantarward. The capsular structures of the metatarsophalangeal joint are then separated from the underlying dermis, and the ray is removed.
- A suture is placed through the capsular structures of the adjacent metatarsal heads. Pressure is then applied to the tibial and fibular aspect of the foot to close the defect between the adjacent metatarsals, and a 0 nonabsorbable suture is used to anchor the capsular structures between the adjacent metatarsals to bring the metatarsals together and narrow the defect between the adjacent rays. A small drain is placed in the defect and brought out through a separate puncture wound distally. The subcutaneous tissue is then closed with 3-0 absorbable sutures placed in interrupted fashion. The skin is closed with 4-0 nylon sutures placed in interrupted fashion.
- A bulky dressing is applied, maintaining even compression across the foot and compressing the adjacent metatarsals to decrease tension on the capsular stitch maintaining the metatarsal heads in close proximity. If the flexor or extensor tendons are not involved with tumor, they can be woven through the metatarsal heads to create a sling to anchor the metatarsal heads in close proximity and maintain the close space between the metatarsal heads.

First Ray Resection with Reconstruction with Autogenous Fibular Graft

- TECH FIG 2 shows a recurrent giant cell tumor of the first metatarsal that was treated successfully with a fibular strut graft. The lateral radiograph shows the healed graft 7 years postoperatively.
- Under epidural anesthesia an incision is made over the first metatarsal. Anterior and posterior fasciocutaneous flaps are made extending to the level of the second metatarsal anterior and posterior. The proximal limb of the incision extends beyond the metatarsal cuneiform joint, and the distal incision extends to the web space.
- Resection consists of the following planes between the first and second metatarsals following the bone in the second metatarsal through the metatarsal cuneiform joint and posteriorly and around the first metatarsal the flexor longus muscle tendon. The distal metatarsal is osteomized at the condyles and proximally just distal to the joint. The tumor mass is removed; the anterior tibial tendon, peroneal tendons, and anterior tibial vessels are preserved.
- Reconstruction is performed with a fibular graft from the midshaft of the fibula of the ipsilateral limb. This is placed within the defect, measuring about 8 cm between the cuneiform and the metatarsal head. Fixation is achieved with two small cortical interfragmentary screws proximally and distally. The hallux is maintained in neutral position.

**TECH FIG 1** • **A.** Skin incision location in a metatarsal ray resection. **B.** Dorsal incision. **C.** Plantar incision. **D.** The plantar flap is longer. It is brought dorsally to cover the bony end of the stump.

**TECH FIG 2** • This example shows a recurrent giant cell tumor of the first metatarsal that was treated successfully with a fibular strut graft. The lateral radiograph shows the healed graft 7 years postoperatively.
PEARLS AND PITFALLS

Indications
- A careful and complete history and physical examination are essential. Preoperative studies are necessary to plan the resection and reconstruction.

Surgical incision
- A long plantar flap results in a better end-bearing stump. The natural cascade of metatarsal lengths should be maintained.

Wound healing complications
- Local wound care with dressings and oral antibiotics are usually sufficient for healing.

Deep infection
- Parenteral antibiotics and surgical débridement may be necessary to treat deep infections. Early diagnosis and treatment can affect outcome.

Contractures
- Postoperative splinting can help prevent contractures. Once a contracture occurs, it is treated with stretching if mild. Serial casting may be needed.

Painful stump
- The end of the bones should be contoured to be smooth. A rasp is effective. Adequate soft tissue coverage will help prevent bony prominence, which may become symptomatic.

POSTOPERATIVE CARE
- After a ray resection, the patient is placed in a well-padded splint. Crutches are used until the sutures are removed. The patient may begin range-of-motion exercises and weight bearing as tolerated.
- Toe amputation patients may ambulate in a postoperative shoe immediately. The sutures are removed at 2 to 3 weeks. A wide comfort shoe is worn and activities are progressed as tolerated.

OUTCOMES
- After a toe amputation at the level of the metatarsophalangeal joint, full preoperative function is regained.
- A cosmetic toe prosthesis may be used if the patient desires one, but it has no functional purpose.
- Ray resection outcomes depend on the number of rays amputated and whether the first ray is involved. A ray resection of the second, third, fourth, or fifth metatarsal does not need shoe modification with a molded insert or filler. Generally, ordinary store-bought shoes that are wide and have adequate cushioning are worn.
- A first ray resection affects the remaining foot function because of loss of the windlass mechanism. Reconstruction of the first ray would prevent this problem.
- Removal of two central rays will leave a narrower foot and shoewear problems.
- Patients with a metatarsal ray or transmetatarsal amputation have better outcomes than patients with a Syme amputation.

COMPLICATIONS
- Wound healing complications are treated with local wound care, elevation, and non-weight bearing. Oral antibiotics may be indicated. If there is skin flap necrosis, débridement with a skin graft may be necessary.
- Superficial infection can be treated with a short course of oral antibiotics.
- Deep infection may require immediate operative débridement of devitalized tissue. Parenteral antibiotics are important to treat this limb-threatening problem. At the time of the débridement, a bone culture should be ordered to help determine the appropriate antibiotic.

REFERENCES

Orthopaedic oncology has made dramatic advances in the past 25 years by developing limb-sparing surgery to the point where 85% to 95% of the patients can be treated with complete resection of their disease while preserving the limb and its function. Despite these recent advances in limb-sparing surgery, approximately 10% of all femoral sarcomas are not amenable to limb-salvage techniques and require an amputation. Disarticulation of the hip for malignant tumors is a rare operation, but it is still needed instead of an above-knee amputation if the tumor cannot be resected using a limb-salvage procedure due to proximal transosseous skip metastases, pathologic fractures, extensive diaphyseal extension, and adjacent large soft tissue masses combined with poor response to adjuvant chemotherapy.

Functional outcome after hip disarticulation is problematic. Jain et al published their results of 80 hip disarticulations. Function on the whole was poor, with only one surviving patient regularly using an artificial limb. Patients after hip disarticulation are left without a leg and without a fulcrum to move an artificial limb. They are likely to suffer loss of self-esteem as well as loss of function and mobility, and they may well suffer from phantom pains. The energy expenditure during mobility after an amputation is much greater than that without an amputation and increases as the amputation level becomes more proximal. In comparison, the energy expenditure after a long below-knee amputation is only about 10% more than that required by a non-amputee. When a patient with a hip disarticulation attempts to use a prosthesis, the energy requirements can then be as much as twice that of a normal ambulator. Those who cannot overcome these significant energy requirements must adapt to the use of crutches, canes, or a wheelchair. Given these factors, any intervention that can reduce the energy expenditures required of amputees might increase their likelihood of prosthetic use.

The stump prosthesis provides a lever arm for hip joint motion. This dramatically lowers the energy consumption of ambulating with a prosthetic limb and thus increases the likelihood of prosthetic use. The first attempt to improve the functional status of patients requiring hip disarticulation for malignant bone tumors was published by Marcove, McMillian, and Nasr in 1979. They used an Austin-Moore prosthesis (Smith and Nephew, Memphis, TN) to convert a hip disarticulation to an above-knee amputation. Over the years, the senior author has used this basic idea and made modifications to develop a technique that involves complete tumor removal and resection of the entire femur (hip disarticulation) followed by reconstruction of a proximal thigh stump (similar to an above-knee amputation stump) using a custom modular “stump” endoprosthesis.

**INDICATIONS**

- Indications for stump prosthesis reconstructive surgery after tumor resection are as follows (FIG 1):
  - Skip metastasis to proximal femur from a primary distal femur osteosarcoma
  - Inability to achieve safe osseous margins with a typical wide resection or above-knee amputation due to tumor extension (the most common indication)
  - Tumor contamination of the proximal medullary canal after pathologic fracture due to tumor in the distal femur and retrograde intramedullary fixation
  - A prerequisite for the operation is uncontaminated soft tissues around the hip, retrogluteal region, and proximal thigh.

**IMAGING AND OTHER STAGING STUDIES**

**Plain Radiography**

- Hip and pelvic imaging to rule out pelvic involvement
- Radiographic analysis of the entire femur

**Computed Tomography and Magnetic Resonance Imaging**

- Pelvic and hip CT scans are done to locate and define the tumor margins. CT helps rule out tumor involvement of the acetabulum.

**Bone Scan**

- A bone scan of the femur is done to determine the extent of the skip metastasis.

**Angiography and Other Studies**

- MRI of the soft tissue of the pelvis and proximal femur is a crucial part of the decision as to whether enough soft tissue...
can be safely spared to reconstruct the proximal thigh stump with adequate soft tissue coverage.

**SURGICAL MANAGEMENT**

- Unique anatomic considerations:
  - Arterial blood supply to the soft tissues must be preserved. The superficial femoral artery should be ligated within the sartorial canal as distally as oncologically possible.
  - The prosthesis must be secured to the hip capsule to avoid dislocation aggravated by gravity pulling on the prosthesis. This requires capsular reconstruction and reinforcement.
  - Modular prosthetic design allows use of a large bipolar cup, modular body length with porous coating to aid in soft tissue ingrowth, and a distal rounded tip designed to avoid tissue penetration with distal muscle fixation holes (FIG 2).
  - Muscle groups of the thigh must be connected distally to the prosthesis with tension balanced properly to avoid the excessively strong pull of the hip flexors and abductors.

**FIG 1** • Indications for hip disarticulation and reconstruction with a stump prosthesis. **A.** Proximal skip metastasis without soft tissue extension. **B.** Corresponding resected pathology gross specimen as seen in (C). **C.** Plain radiograph of a distal femoral nonunion after a pathologic fracture that was treated with a long retrograde intramedullary nail. **D.** Distal femoral synovial sarcoma with a proximal femoral head skip metastasis.

**FIG 2** • A modular stump prosthesis consists of a proximal bipolar head, porous coating, and holes to reconnect the hip capsule and abductor mechanism. The prosthesis body comes in different lengths. The distal tip is rounded to avoid penetration of tissues. Distal holes are used to anchor down the distal muscle ends.
Sufficient soft tissue coverage of all the prosthesis, and specifically its distal part, is critical.

Phantom pain and stump pain should be addressed initially by placing an epineural catheter in the transected sciatic nerve and using multimodal analgesia.

**Preoperative Planning**

- MRI and CT are done to determine the extent of the tumor in the proximal femur.

**HIP EXPOSURE AND VASCULAR DISSECTION**

- The patient is placed supine on the operating table. A two-armed incision is made starting medially and extending distally along the medial side of the distal femur. This incision should be relatively posterior so that the sartorial canal and the superficial femoral artery are accessed through their posterior aspect, leaving the anterior branches to supply the anterior flap and quadriceps muscle (similar to an anterior flap hemipelvectomy). The lateral portion of the incision is directed toward the greater trochanter and extends down the lateral portion of the femur in line with the course of the fascia lata.

- The incision and approach to the hip may vary depending on the type of flap. The initial incision is carried down through the subcutaneous fat and fascial layer to reveal the external oblique aponeurosis using large anterior myocutaneous flaps (TECH FIG 1). Multiple branches of the saphenous vein are usually encountered; these should be clamped, divided, and ligated.

- Once the superficial femoral artery is identified, it is clamped, divided, and ligated as distally as oncologically possible. The accompanying vein and nerve are also ligated. The sartorius is identified at its origin at the anterior superior iliac spine and divided from its origin. Next the hip is flexed to relax the iliopsoas muscle, which is identified and dissected from its origin.

**Anterior Flap Dissection**

- Large anterior and posterior flaps are developed. The fascia lata is incised along its entire length. The vastus lateralis is released from its origin.

- With the fascia lata exposed, the hip girdle muscles are visualized with internal rotation of the hip.

- The sciatic nerve is identified and a Penrose drain is placed around the nerve. The next steps involve dissecting the bone away from the musculature distally.

- Distally, the quadriceps muscles, the adductor muscles, and the hamstring muscles are sequentially clamped using large Kelly clamps and divided according to a predetermined anatomic level of the above-knee amputation. They are marked with Dacron tape (Deknatel, Mansfield, MA).

**Hip Disarticulation**

- A trochanteric osteotomy is made with the abductors detached with the osteotomy fragment. The osteotomy is recommended as long as there is no tumor involving the greater trochanter and surrounding area. An appropriate angle should be maintained while the osteotomy is being performed to ensure that an adequate amount of bone remains attached to the abductor musculature.

- The short external rotators are divided at their bony insertions.

- The hip capsule is identified and divided at the base of the femoral neck using a standard T-type incision. The base of the T runs along the anterior part of the neck. The T itself is circumferential along the base of the neck.

- The hip capsule is tagged for later reconstruction.

- The sciatic nerve is located at the level of the hamstring. It should be cut 2 cm proximal to where the hamstrings are cut. By maintaining the proximal sciatic branches, innervation to the hamstrings is maintained and thus hip extension is preserved. The hip is disarticulated at the acetabular level at this point and the entire femur is removed (TECH FIG 2).

**Creating a Femoral Stump with a Proximal Femoral Modular Prosthesis**

- The proximal femoral modular prosthesis comprises a proximal bipolar part, a body, and a distal rounded tip. The proximal bipolar part has holes and porous coating around the base of the neck that is intended for reattaching the hip capsule and the greater trochanter. This prevents sliding of the transferred muscles.

- The prosthesis body has variable length options. The correct length is chosen according to trial measurements.

- The distal conical tip is custom-made to fit the prosthetic body. It has a rounded bullet-shaped tip to avoid pene-
The whole proximal femur is exposed, disconnected from the hip capsule, and removed. Muscle ends and hip capsule are tagged as they are disconnected.

A trial proximal femoral prosthesis can be assembled based on an approximation of the required length. The resected femoral head should be measured to help approximate the head cup size that is required. The trial prosthesis should be placed into the acetabulum and the soft tissues should be released from their retracted positions to simulate closure and demonstrate whether the trial prosthesis will allow adequate soft tissue closure (TECH FIG 3). Once the desired prosthesis is determined, the prosthesis is assembled and the Morse tapers are impacted.

To strengthen the capsular closure, we use 3-mm Dacron tape, which acts as a noose around the prosthesis to prevent dislocation. This step is often easier if done just before the actual prosthesis placement.

The Dacron tape is sewn circumferentially around the cut capsule (TECH FIG 4). Putting too much tension on the Dacron tape may cause difficulty in reducing the prosthesis. Once the Dacron is in place, the assembled prosthesis is reduced into the acetabulum and the Dacron is snugly tightened and tied, forming a noose around the femoral neck. In our experience this has helped to prevent dislocations.

The hip joint should be put through functional range of motion to ensure a successful outcome.

Once the surgeon is satisfied with the prosthesis and range of motion, the previously detached iliopsoas muscle is pulled over the anterior hip capsule and sutured to it with Ethibond. The short external hip rotators are pulled anteriorly and sutured to the posterior capsule.
Reconstruction of the Adductor and Abductor Mechanism

- The hip abductors with the osteotomized greater trochanter are repositioned and reconnected with cables and a greater trochanter grip (TECH FIG 5A). The adductors are reconnected to the stump stem (TECH FIG 5B, C).
- The remaining proximal portion of the sciatic nerve is identified. Its epineural sheath is opened carefully using a fine right-angle clamp, and a standard epidural catheter is placed and threaded proximally for at least 5 to 10 cm within the sheath. The catheter is then sutured to nearby adipose or muscular tissue to help secure it using a 4-0 chromic suture. A 14-gauge angiocatheter is placed at the desired exit point for the catheter, with the needle passing beneath the subcutaneous and muscular layers. The epineural catheter is threaded through the angiocatheter to its desired position at the skin level and the angiocatheter is removed with the epineural catheter now outside the skin. The catheter should be infused with 4 to 8 cc 0.25% bupivacaine without epinephrine to aid in postoperative pain control.

Soft Tissue Reconstruction and Wound Closure

- Dacron tapes are sutured into all cut distal stumps of the quadriceps, adductors, and hamstrings (TECH FIG 6).
- The posterior muscle groups are tenodesed to the stump prosthesis using the holes made into the distal portion of the prosthesis with the hip in complete extension. The quadriceps muscle is tenodesed to the anterior portion of the stump prosthesis in a similar fashion through the preformed holes, also with the hip in extension. The adductor group is connected in a similar fashion. By setting the prosthesis in neutral position and pulling all three groups and tenodesing them at once, muscle balance is achieved.
- The surgeon should avoid hip flexion and adduction.
- The ends of the muscles are sutured to each other, forming a continuous fascial border covering the distal stump. Appropriate muscle tensioning and balancing are imperative to prevent muscle contractures, particularly abduction and adduction or flexion contractures.
- The reconstructed stump should lie in neutral position. The origin of the vastus lateralis is reattached to the greater trochanter proximally. The vastus lateralis fascia is tenodesed to the fascia lata.
- We favor the use of two Jackson-Pratt drains to drain the wound at the deep layers of the hip joint and the distal stump (TECH FIG 6D).
- The fascia lata is reapprroximated along its entire length. The subcutaneous and skin layers are then closed using standard techniques.
- A compressive dressing is recommended to prevent excessive swelling. The stump should remain in neutral position if the tissue tension is balanced correctly.
Fasciocutaneous flaps to supply adequate cover
- An anterior flap is preferred, but if this is not possible then a posterior flap is used.

Sparing the abductor mechanism with a greater trochanter osteotomy
- As long as no disease involves the area of the greater trochanter, this should be osteotomized and used in reconnecting the abductor mechanism.

Trial prosthesis
- Measurements should be made intraoperatively for the bipolar head size and body length of the prosthesis.

Hip capsule
- Hip joint capsule should be preserved and tagged. After resection the capsule should be reconnected to the prosthesis around the base of the neck. The hip capsule is then reinforced by connecting the distal end of the psoas muscle to the anterior capsule and the short external rotators to the posterior capsule.

Muscle tension
- The quadriceps, hamstrings, and adductor muscles should be reconnected at equal tension while the prosthesis is in neutral position.

Sciatic epineural catheter
- Postoperative analgesia is crucial. We believe pain should be treated perioperatively by inserting an epineural catheter into the transected tip of the sciatic nerve.
POSTOPERATIVE CARE

- Drains may be removed about 3 days after surgery. Compressive dressings are used for the first few weeks after surgery. A prosthesis may be fitted as soon as the wound has healed. Full weight bearing is permitted.
- Physiotherapy may begin promptly after surgery and should focus on achieving range of motion.

OUTCOMES

- We have used this procedure in six patients over a 30-year period for osteosarcoma (n = 2), malignant fibrous histiocytoma of bone (n = 2), and synovial sarcoma (n = 2), with very good results. Five of the six patients ambulated with an above-knee prosthesis (FIG 3). The only patient who did not ambulate with his prosthesis died within several months of the surgery due to complications from his disease.
- There were no infections, no dislocations, and no local recurrences; no secondary procedures were required in any of these patients.
- Three patients died of their disease and three patients remain alive. Of the three remaining patients, one has been ambulating with his stump prosthesis for 15 years.

COMPLICATIONS

- A possible complication is deep infection involving the prosthesis. Stump reconstruction should be undertaken only when it is evident there is no infection of the limb. If there is doubt about infection, a two-stage procedure is recommended.
- To avoid hip dislocation, the hip joint capsule must be reconstructed. The reconstructed hip is then reinforced with the psoas anteriorly and the short external rotators posteriorly. Stability should be assessed intraoperatively.
- There is a natural tendency for the stump toward flexion and abduction due to the muscle strength of the quadriceps and abductors. It is therefore crucial to achieve muscle balance of the quadriceps, adductors, hamstrings, and abductors during reconstruction.

REFERENCES

BACKGROUND

- Although many bone and soft tissue sarcomas of the femur and thigh can be treated with limb-sparing techniques, some aggressive tumors are complicated by neurovascular involvement or extensive soft tissue contamination and thus require an above-knee amputation (AKA) (FIG 1).
- An AKA is a transfemoral amputation of the lower extremity. AKAs are usually classified by level: high (just below the lesser trochanter), standard or midfemur (diaphyseal), or low distal femur (supracondylar).
- In general, transfemoral amputations with 50% to 70% of the residual bone length (measured from the greater trochanter to the lateral femoral condyle) are optimal. However, when amputations are done in an oncologic setting, the amount of femur remaining is determined by the extent of the tumor.
- Generally if 3 to 5 cm of bone distal to the lesser trochanter remains, a standard AKA prosthesis can still be used.

ANATOMY

- The surgeon must be familiar with the major neurovascular structures of the thigh because these structures will need to be identified and ligated. The femoral artery is the main artery of the thigh and femur. Its course changes throughout the length of the femur, and therefore its location varies depending on the level of amputation (FIG 2).

High AKA

- Proximally, the femoral artery lies beneath the sartorius muscle, anterior to the adductor longus muscle and anterior to the femur. The profunda femoris artery lies posterior to the adductor longus muscle. At this level the femoral artery is lateral to the femoral vein. The sciatic nerve lies posterior to the adductor magnus and anterior to the long head of the biceps.

Midfemur AKA

- The femoral artery lies between the vastus medialis and the adductor magnus and is medial to the femur in the mid thigh area. In this region, the femoral vein is lateral to the artery. The sciatic nerve lies between the short head of the biceps and the semimembranosus.

Supracondylar AKA

- The femoral artery is directly posterior to the femur. After passing the canal of Hunter, the femoral artery joins the sciatic nerve in the popliteal fossa. The artery is deep and medial to the sciatic nerve.

INDICATIONS

- Local recurrence of malignant carcinoma or sarcoma where limb salvage would not yield a functional limb or effectively remove the disease (FIG 3).
Chapter 40  ABOVE-KNEE AMPUTATION  2061

- Tumors with major vascular involvement with invasion of major blood vessels, which usually have poor outcomes and a poor prognosis
- Soft tissue contamination, such as after a pathologic fracture
- Tumors of the distal lower extremity with major nerve involvement, as with tumors of the popliteal space (FIG 4A,B)
- A poorly planned and executed biopsy, which can cause extensive contamination
- Infection, particularly in the case of biopsy, which can cause extensive contamination
- Skeletal immaturity, which often leads to significant limb-length discrepancies when limb-sparing procedures are done on skeletally immature patients
- Extensive tumor involvement that prohibits adequate soft tissue coverage of a prosthesis (FIG 4C–E)

IMAGING AND OTHER STAGING STUDIES

Plain Radiography
- Plain radiographs often provide the first indication for the need for amputation and an initial estimate of the necessary amputation level.
- Orthogonal views of the femur, tibia, and fibula can be helpful in showing tumor involvement and the extent of bony destruction, although generally up to 30% of the bony architecture has to be destroyed before radiographic findings are apparent (FIG 5A).

Computed Tomography and Magnetic Resonance Imaging
- CT and MRI are the most helpful in determining the level of intramedullary tumor involvement and the extraosseous extent of the tumor, which is used to determine the amputation level (FIG 5B).
- MRI is also useful for showing tumor involvement of neurovascular structures, which often necessitates amputation. MRI is the most reliable imaging study in determining the presence of skip metastases, which may alter the level of amputation.

FIG 2 • Level of osteotomy and cross-sectional anatomy for supracondylar, diaphyseal, and high above-knee amputation. (Courtesy of Martin M. Malawer.)

FIG 3 • A. A 45-year-old patient initially presented with a dedifferentiated, high-grade osteosarcoma of the fibula. After neoadjuvant chemotherapy the patient underwent intercalary fibular resection. Approximately a year after the surgery the patient presented with a rapidly enlarging, extensive tumor recurrence. B. As shown on MRI, the tumor extensively invaded the superficial posterior, deep posterior, and lateral compartments of the leg. Wide excision of the tumor would necessitate removal of the neurovascular bundle and all three compartments. Above-knee amputation was therefore performed.
FIG 4 • A, B. A 77-year-old patient presented with a high-grade soft tissue sarcoma that invaded the popliteal space and destroyed the proximal and midshaft areas of the tibia and fibula, resulting in the loss of peroneal function. C. A 23-year-old patient with a few years’ history of a neglected benign giant cell tumor of the distal femur with an extensive soft tissue component. D. A plain radiograph of the distal femur showing extensive bone destruction. The knee joint is in flexion contracture due to intractable pain. E. CT shows that only a thin rim of muscles is left. Adequate soft tissue coverage of a prosthesis was therefore not feasible, and above-knee amputation was performed. (C–E: Courtesy of Martin M. Malawer.)

FIG 5 • A. Plain radiograph of the knee showing extensive destruction of the proximal tibia and fibula. B. CT scan showing a large tumor that displaced the popliteal artery posteriorly and obliterated branches of the popliteal artery more distally.
Bone Scan
- Bone scans are useful in determining the intraosseous extent of the tumor; findings correlate well with the MRI.

Angiography and Other Studies
- Angiography is useful in determining the patency of the major vessels. In the older population, the superficial femoral artery is often obliterated.

Biopsy
- A biopsy is necessary before determining the final level of amputation. In general, transmedullary amputation is now performed for bony sarcomas of the distal femur, although historically a hip disarticulation was recommended. A failed limb-sparing procedure of the distal femur can still be treated with a high AKA.

Surgical Management
- When AKAs are done for oncologic indications, the tumor extent ultimately determines the level of amputation. Beyond that consideration, retaining as much length as possible that is closest to the ideal stump length will facilitate prosthetic fitting. The types of flaps may vary depending on the extent of the distal femoral tumor; medial-lateral flaps may be required instead of the more traditional fish-mouth incision. The quality of the skin, prior radiation, and old scars must all be considered. In general we do not use immediate-fit prostheses after amputation for tumors.
- When planning the types of flaps that will be used for the amputation, the surgeon should consider the soft tissue extent of the tumor, prior radiation fields, and previous incisions.

Preoperative Planning
- Having patients meet with a prosthethist, a functional amputee, or both can help manage expectations and answer specific questions about daily activities and function.

Positioning
- Patients are placed supine on the operating table with the operative extremity in flexion and abduction (Fig 6).

Approach
- Most amputations are done initially using an anterior approach to the femur. The leg can then be placed in a figure-4 position and then flexed and adducted to facilitate the posterior work.

Incision and Transection of Muscle, Neurovascular Structures, and Bone
- The most common type of flap is the anterior and posterior fish-mouth flap. This type of incisional line should be drawn before starting the procedure. The initial incision is made through the skin, superficial fascia, and subcutaneous tissue vertical to the skin edges (Tech Fig 1A).
- The major muscles should be carefully transected using electrocautery to reduce bleeding and tacked for later use in soft tissue reconstruction. The level of the amputation will determine the muscles that are transected, but portions of the quadriceps, hamstrings, and adductors are cut at almost all levels (Tech Fig 1B).
- The deep femoral artery and vein are dissected, suture-ligated, and transected.
- Nerves should be pulled gently about 2 cm, ligated with nonabsorbable sutures, and transected with a knife. The sutures can be used later to identify the femoral and sciatic nerves if epineural catheters are to be placed. If the catheters are not placed, the nerves should be allowed to retract back to the muscle mass.
- The bone is cut using an oscillating or Gigli saw. A malleable retractor placed posterior to the femur can prevent damage to the posterior soft tissue and flap. Once the bone is cut, frozen section analysis from the remaining intramedullary canal is performed to ensure that there is no tumor remaining.
- The femoral edge is beveled using a saw or rasp to smooth the remaining edge and to leave a less prominent point of contact for the prosthesis (Tech Fig 1C, D).

Placement of Epineural Catheter and Myodesis
- A small opening is made using a 15-blade scalpel into the epineural sheath. An epineural catheter, which has previously been flushed with 0.25% bupivacaine, is introduced into the epineural space and advanced proximally for 5 to 7 cm. The neural sheath is then closed with 4-0 chromic suture (Tech Fig 2A, B).
- A 16-gauge angiocatheter is introduced into the skin at the desired site of exit for the epineural catheter. The epineural catheter is threaded through the angiocatheter until it is visible beyond the skin. The angiocatheter, encasing the epineural catheter, is carefully brought through the subcutaneous tissue to exit at the skin.
- To prevent flexion and abduction of the femoral stump, drill holes can be made in the femur using a standard drill, and then the sutures used to tag the adductor musculature can be threaded through the femoral holes to tenodese the adductors to the femur. This also helps restore some of the muscular strength (Tech Fig 2C).
Part 5 ONCOLOGY • Section IV LOWER EXTREMITIES

TECH FIG 1 • A. Incision. The skin flaps are marked. The main factors that determine the type of flaps are the extent of the soft tissue tumor, areas of prior radiation, and previous scars. The highest priority is to avoid local recurrence, and no attempt is made to adhere to standard flaps; at this level a skin or muscle flap of almost any length will heal primarily in a young patient. It is not necessary to use equal flaps; long posterior, anterior, and medial flaps will heal. B. Transection of muscle and bone. Incision is performed through the skin, superficial fascia, and subcutaneous tissue vertical to the skin edges. Using electrocautery, muscles are beveled in their transection down to bone. Large vessels are dissected, suture-ligated in continuity, and transected in a bloodless fashion. Nerves should be gently pulled down from their muscular bed approximately 2 cm, ligated with nonabsorbable monofilament sutures, transected with a knife, and allowed to retract back to the muscle mass. The bone is transected with an oscillating or Gigli saw without traumatizing the soft tissues. C. The femoral edge should be beveled and smooth. D. A sharp edge can become extremely painful, especially when pressure from a prosthesis is applied. (Courtesy of Martin M. Malawer.)

- We recommend excising some of the adductors before myodesis to shape the stump into a nice conical shape. Additional muscle may be resected from the lateral aspect of the thigh if necessary.
- A plug of polymethylmethacrylate (PMMA) or Gelfoam is placed in the distal canal to prevent large hematomas from occurring due to continuous intraosseous bleeding after surgery. This is more common in young adults and children.
- The remaining quadriceps and hamstring muscles are myodesed to each other to cover the end of the femur.

Drain Placement and Closure
- Closed suction drains placed beneath the fascial layer should be brought out of the medial and lateral aspects of the incision (TECH FIG 3A).
- The superficial fascia should be tightly closed. As the skin edges are closed, the surgeon should take care to avoid having excess tissue and large skin folds, which can later interfere with optimal prosthesis fitting.
- A rigid dressing should be applied at the completion of the amputation to reduce swelling and prevent the development of a flexion contracture (TECH FIG 3B).
**TECH FIG 2** • A. An epidural catheter, flushed with bupivacaine 0.25%, is introduced into the epineural space. The catheter is advanced 5 to 7 cm proximally, and the neural sheath is sutured over the catheter with absorbable sutures. B. An epineural catheter in the femoral nerve after above-knee amputation. Contrast dye was bolus injected to show the distribution of local anesthetics within the epineural space. C. A two-layer myodesis is used over the end of the femur. Muscle stabilization of the femur is essential if the strength of the limb is to be retained. The quadriceps and hamstring muscles are myodesed to each other to cover the bony end of the femur, and the adductors are tenodesed to these muscles and the femoral stump using drill holes. This is especially important if there is a short proximal femoral stump, which tends to go into flexion and abduction. (Courtesy of Martin M. Malawer.)

**TECH FIG 3** • A. Closed suction drains are brought out of the medial and lateral aspects of the incision. It is important not to stitch these catheters to the skin, because they will be removed from inside the rigid dressing. B. Application of a rigid dressing. (Courtesy of Martin M. Malawer.)
PEARS AND PITFALLS

Postoperative flexion contracture  ■ Flexion contractures can be prevented with the use of proximal casting or immobilization to the groin level, suspended in place with a belt, if necessary.

Adductor myodesis  ■ After AKA the iliopsoas and hip abductors can cause the stump to go into flexion and abduction. Tenodesing the adductor magnus prevents this deformity and helps prevent the loss of hip abduction power, which has been estimated to be up to 70% less without myodesis. Myodesis acts as an insertion site and facilitates muscle contraction and function.

Muscle balance  ■ Managing muscle group imbalances through myoplasty also improves the function of the amputee. Because the hip flexors are stronger than the extensors, the hamstrings should be cut longer than the quadriceps and attached to one another.

Neuroma  ■ Nerves should be cut as proximally as possible and buried within muscular tissue to prevent neuroma formation.

Phantom pain  ■ The use of epineural catheters in the femoral and sciatic nerves can decrease the incidence and severity of phantom pain.

Skin pressure from bone edges  ■ The distal anterior cortical edge of the femur should be beveled to prevent pressure arising from the bone, particularly with prosthetic use.

POSTOPERATIVE CARE

■ A compressive dressing applied to the stump site diminishes postoperative swelling at the stump site.
■ Proximal extension of the postoperative immobilizer or splint, prone positioning, and physical therapy help to prevent flexion contracture.
■ Fitting for an initial or temporary prosthesis soon after wound healing and swelling resolution is most often associated with increased prosthetic use.
■ Because the energy requirements of AKAs are about 60% to 100% times greater than that required for non-amputees, many amputees require the use of assistive devices for ambulation.
■ Phantom limb pain and sensations can diminish after surgery. However, when phantom pain persists, narcotics and drugs with effects on nerves such as gabapentin (Neurontin) may be helpful.

OUTCOMES

■ Through effective multidisciplinary care, most patients are able to ambulate and return to normal daily activities, including driving. Some are also able to participate in sporting activities.
■ Outcome studies comparing patients treated with amputations versus those treated with limb salvage found that AKA amputees were more limited in their mobility and community activities compared to those with limb salvage, but they reported less muscle weakness. In general, AKA amputees have approximately the same overall quality of life compared to patients undergoing limb-sparing surgery when assessed by numerous psychological measures.
■ AKA amputees have also been shown to be more likely to walk with a limp.

COMPLICATIONS

■ Wound healing problems can arise but are not as common as in amputations performed for vascular or ischemic problems. Wound problems after amputations performed for tumors are most likely due to preoperative host factors such as comorbidities and nutritional status. Therefore, the patient’s preoperative status should always be optimized where possible.
■ Phantom pain or causalgia syndromes may occur and are difficult to predict, although patients with significant preoperative pain complain of postoperative pain more often. Attempts at preventive anesthesia (eg, serial epidurals before surgery) have produced mixed results. It is important to identify and diagnose these painful syndromes early and manage them aggressively.

REFERENCES
BACKGROUND

- Extensive tumors of the distal leg, ankle, and foot often require a below-knee amputation (BKA) as the primary form of surgical treatment. With such extensive tumors in these locations, attempts at limb salvage often leave patients with a limb with very limited function. Conversely, advances in prosthetic design and engineering allow for BKA amputees to be very active in a variety of activities, often more active than patients who have had limb-sparing procedures for similar tumors.
- In general, we recommend BKAs for most high-grade and many low-grade sarcomas of the foot, especially when they occur in the plantar aspect. About 1% of bone sarcomas occur in the foot; these are usually treated with a BKA (FIG 1).

ANATOMY

- The main anatomic focus of a BKA is identification and ligation of the tibial neurovascular structures.
- The anterior tibial artery and vein and deep peroneal nerve lie deep to the anterior tibialis muscle and lateral to the tibia. These structures must be identified and individually ligated.
- As the dissection progresses posteriorly, the posterior tibial artery and vein and tibial nerve are found posterior to the tibia and tibialis posterior muscle and anterior to the soleus muscle.
- The peroneal artery and veins also lie posterior and lateral to the tibia. They lie between the tibialis posterior and the flexor hallucis longus.
- The superficial peroneal nerve is identified within the lateral compartment of the leg and also must be transected. It usually exits the fascia of the anterolateral leg approximately 12 cm proximal to the tip of the lateral malleolus. It should be identified and transected.

INDICATIONS

- Tumor recurrence in the distal tibia, ankle, and foot not amenable to limb-salvage techniques (FIG 2)
- Infiltrative high-grade soft tissue sarcomas or other malignant tumors of the lower extremities.
- Extensive involvement of bone sarcomas of the lower extremities
- Palliation
- Failed attempt of radiation therapy for dorsal and plantar foot tumors

IMAGING AND OTHER STAGING STUDIES

Plain Radiography

- Although plain radiographs are poor at identifying soft tissue tumors of the foot and ankle, they can be useful for the initial diagnosis of bone tumors such as enchondromas, giant cell tumors, and primary sarcomas of bone (FIG 3A).

Computed Tomography and Magnetic Resonance Imaging

- CT and MRI are helpful in determining the level of intramedullary tumor involvement and the extraosseous extent of the tumor, which is used to determine the amputation level. MRI is also useful for showing tumor involvement of neurovascular structures, which often necessitates amputation (FIG 3B).

Bone Scan

- Bone scans are required if the tumor is located at or above the ankle. This study correlates well with the MRI. In general, amputation is performed 4 to 7 cm above abnormal findings on a bone scan.

Angiography and Other Studies

- Angiography is very helpful in determining the extent of involvement of the anterior tibialis and posterior tibialis arteries. Tumor involvement of either of these structures determines the type of flap that should be used. This planning is important in minimizing wound healing problems.

Biopsy

- As with an amputation at any level, a biopsy should be done to confirm the diagnosis before performing a BKA.

SURGICAL MANAGEMENT

- The ideal level of surgical resection for a BKA is at the musculocutaneous junction of the gastrocnemius muscle. This provides better soft tissue padding and usually a more reliable blood supply for the posterior flap.
- The recommended length for a BKA stump for optimal prosthetic fitting is 12.5 to 17.5 cm. However, tumor extent and margins will ultimately determine the length of the stump.
- Careful flap selection is important in achieving a functional BKA stump. Because of the subcutaneous location of the tibia and sparse musculature of the anterior leg compartment, use of a long posterior flap is preferable to a fish-mouth flap.
- Prevention of hematoma and seroma development with the use of drains is critical. These complications can delay wound healing and in some cases delay adjunctive treatments such as chemotherapy and radiation therapy.

Preoperative Planning

- Preoperative referrals to a psychologist and prosthetist are often useful in helping patients prepare for their upcoming life adjustments.

Positioning

- The patient is supine on the operating table with the operative extremity slightly elevated.

Approach

- The initial approach is made anteriorly in most cases. Then the knee can be flexed and abducted and adducted or an assistant can elevate the leg to gain exposure for the posterior work.
FIG 1 • Below-knee amputation is performed for malignant tumors of the distal leg, ankle, and foot. (Courtesy of Martin M. Malawer.)

FIG 2 • A. Locally recurrent carcinoma of the foot. This local recurrence, the patient’s fifth, occurred only a few months after the previous resection within the irradiated field. B. Extensive high-grade angiosarcoma of the dorsal aspect of the foot. (Courtesy of Martin M. Malawer.)

FIG 3 • A. Angiosarcomatosis of the leg and foot. There are multiple lytic lesions of the distal third of the tibia, fibula, and talus. B. T2-weighed MR image of the foot, showing extensive high-grade malignant fibrous histiocytoma of almost the entire plantar aspect of the foot, with extension to the dorsal aspect of the foot.
Incision and Flap Selection, Soft Tissue Dissection, and Bone Transection

- Because of the subcutaneous location of the tibia and the minimal musculature of the anterior leg compartment, a long posterior flap is preferable to the classic fish-mouth flap. In the initial incision, the skin, superficial fascia, and subcutaneous tissue are cut perpendicular to the skin surface (TECH FIG 1A).
- The muscles of the anterior, lateral, and deep compartments of the leg are transected using the electrocautery to minimize bleeding.
- The skin, superficial fascia, and subcutaneous tissue are cut perpendicular to the skin surface. The muscles are transected with electrocautery. Vascular structures are ligated in continuity and divided. Major blood vessels are suture-ligated (TECH FIG 1B). Nerves are meticulously dissected and gently pulled 2 cm out of their surrounding muscle mass. They are double-ligated with monofilament nonabsorbable suture. The large muscle groups are tapered so that they can be secured over the cut ends of the bone. If the amputation is performed for a primary bone sarcoma, intramedullary content from the edge of the stump should be sent for frozen section to verify that it is free of tumor. If the amputation is performed for a soft tissue sarcoma, soft tissues from the surgical margins should be assessed in a similar manner. After transection, the tibial edge is beveled (TECH FIG 1C,D).
- The tibia is osteotomized using an oscillating or Gigli saw. The fibula is resected several centimeters proximal to the tibial osteotomy to create a more tapered stump. The cut edge of the tibia is beveled using a saw or rasp to smooth the edges and contour the bone for a better prosthetic fit (TECH FIG 1C).
- A sample from the remaining intramedullary canal of the tibia should be sent for frozen section analysis to verify that the remaining bone is free of tumor.
- To form a nice conical stump, we recommend excising the fibula about 4 to 5 cm above the tibial osteotomy, in addition to removing some of the peroneal musculature at the same level. This permits easier stump shrinking and prosthetic fit.

Placement of Epineural Catheter and Myodesis

- A small opening is made using a 15-blade scalpel into the epineural sheath. The epineural catheter, which has previously been flushed with 0.25% bupivacaine, is intro-
PEARLS AND PITFALLS

<table>
<thead>
<tr>
<th>Stump contour</th>
<th>■ Rounding the contour of the distal end of the tibial stump and resecting the fibula a few centimeters shorter than the tibia can promote better fit and ease with prosthesis use.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Myodesis</td>
<td>■ Functional myodesis of the major muscle groups of the leg to the distal tibia provides good soft tissue coverage for the stump while allowing functional range of motion.</td>
</tr>
<tr>
<td>Wound healing problems</td>
<td>■ Healing can be compromised by preoperative chemotherapy. The use of drains and attention to detail with wound closures can help avoid these problems as well as hematoma and seroma development, which can delay other adjunctive treatments.</td>
</tr>
<tr>
<td>Postoperative flexion contracture</td>
<td>■ The use of a knee immobilizer or custom splint can prevent the development of a flexion contracture.</td>
</tr>
<tr>
<td>Phantom pain and causalgia</td>
<td>■ Perineural catheter flow rate, dose should be titrated, typically 4 to 8 mL of 0.25% bupivacaine per hour for about 72 hours.</td>
</tr>
</tbody>
</table>
POSTOPERATIVE CARE

- Once the initial postoperative dressing is removed, a stump-shrinker sock can be worn to minimize swelling.
- Patients should be counseled that the transition to prosthesis use will be slow and gradual and will occur over about 3 to 6 months. Once an initial prosthesis can be fitted, wear time is gradually increased to build tolerance.

OUTCOMES

- Similar to other lower extremity amputations, BKAs have been shown to be effective in palliation and improving the quality of life in cancer patients.
- As might be expected, patients after BKAs report less limitations than their AKA counterparts and are less likely to ambulate with walking aids or a limp.
- The vast improvements in prosthetic design for BKA amputees allow them to be extremely functional. They can participate in almost any desired recreational activity.

COMPLICATIONS

- Hematoma and seroma develop can cause major wound healing problems that sometimes require additional surgeries. This is a major problem when the amputation has been done for a primary bone or soft tissue sarcoma and adjuvant chemotherapy is needed. Such wound problems can delay the start of these very important treatments and ultimately also delay prosthetic fitting. The use of closed suction drains can minimize the risk of such complications.

Foot and Ankle Amputations: Lisfranc/Chopart

Loretta B. Chou, H. Thomas Temple, Yvette Ho, and Martin M. Malawer

BACKGROUND

- Tumors of the foot and ankle are rare. In the senior author’s experience, 153 cases were treated.
- FIGURE 1A shows all anatomic sites, FIGURE 1B shows the distribution of malignant and benign cases, and FIGURE 1C shows the distribution of all types of surgical procedures.
- Patients with tumors of the metatarsals complain of pain with an associated mass. The mass may be small and chronic. It may be first noticed after a minor injury. The patient may have difficulty with weight-bearing activities, including walking and standing. Shoe wear, particularly fashionable shoes, may be limited.
- Physical examination often shows a tender mass localized to the metatarsal with some swelling. If a sensory nerve overlies the mass, there may be paresthesias. If the mass is large, there may be loss of motion, or discomfort with active range of motion of the foot and ankle.
- For extensive disease of the forefoot involving the first and second interspace in adjacent metatarsals or multiple metatarsals, a Lisfranc amputation or a transmetatarsal amputation is indicated (FIG 2A–C). These amputation levels are highly functional with minor shoe-wear modifications and forefoot fillers. If the metatarsal bases can be preserved using a transmetatarsal amputation, the functional outcome is improved.
- Careful preoperative evaluation is necessary, and MRI is especially important to assess the extent of marrow change in the metatarsals to ascertain the appropriate level of amputation.
- For tumors extending to the tarsometatarsal joint with soft tissue extension, a Chopart amputation is a consideration. The Chopart amputation is a transtarsal amputation that preserves the talus and calcaneus. The disadvantage of the Chopart amputation is the loss of the dorsiflexors of the foot, which allows unopposed action of the Achilles tendon, resulting in an equinus contracture.
- To circumvent this problem, the tibialis anterior is used. It is detached from the tarsal navicular with a cuff of soft tissue, preferably periosteum. A drill hole is made through this bone tunnel and sewn to itself or soft tissue as it exits through the tunnel. The repair may be augmented with bone anchors placed near the dorsal opening of the tunnel. The residual foot is maintained in maximal dorsiflexion (FIG 2D,E).
- The advantage of a Chopart amputation over a Syme amputation is the maintenance of hindfoot height. This is an end-bearing residual limb and the patient can negotiate short distances without modified shoe wear or prosthetic fitting.

ANATOMY

- The Lisfranc joint is the tarsometatarsal joint. An amputation at this level will preserve the dorsiflexors and plantarflexors.
- The Chopart joint is also known as the transverse tarsal joint. It includes the talonavicular and calcaneocuboid joints. An amputation at this level preserves the plantarflexors but sacrifices the dorsiflexors, often resulting in an equinus contracture.

INDICATIONS

Lisfranc

- Extensive tumor involving the first and second interspace in adjacent metatarsals or multiple metatarsals

Chopart

- Tumors extending to the tarsometatarsal joint with soft tissue extension. FIGURE 3 shows the pathology specimen after wide resection of a chondrosarcoma involving multiple small bones of the foot.

IMAGING AND OTHER STAGING STUDIES

- Preoperative studies include plain radiographs of the foot, including anteroposterior, lateral, and oblique views. If there is involvement of the ankle joint, then anteroposterior and mortise views are obtained as well. MRI is important to evaluate the amount of involvement of the metatarsals to determine the level of amputation. It also shows the extent of soft tissue tumors and may be helpful in distinguishing benign from malignant tumors.
- MRI is helpful for assessing soft tissue involvement. FIGURE 4A,B shows a chondrosarcoma of the calcaneus, and the MRI shows extension into the soft tissue. It was treated with cryosurgery but recurred, and a below-the-knee amputation was performed.
- FIGURE 4C,D shows an example of a unilateral calcaneal brace (UCB). The radiograph shows the typical expansile appearance of the UCB. The CT scan shows greater bony detail. The lesion was treated with curettage, graft, and polymethylmethacrylate (PMMA).

SURGICAL MANAGEMENT

- The goal of the surgical procedure is remove the tumor with adequate margins. FIGURE 5 illustrates a case of osteosarcoma of the calcaneus. Osteosarcoma is usually treated with wide resection, but in this case the tumor was confined to the calcaneus. The patient had a good response to adjuvant chemotherapy, with 100% tumor necrosis, and was treated with the only calcaneal prosthesis reported in the world.
- A long plantar flap is important for a sturdy end-bearing stump.
- The quality of the tissue is more important than the quantity. The bony edges should be smooth and beveled if possible. An example is the Lisfranc amputation, in which the cuneiforms...
FIG 1 • A. All anatomic sites of tumors of the foot and ankle (n = 153). B. Distribution of malignant and benign tumors of the foot and ankle (n = 153). C. Distribution of surgical procedures for tumors of the foot and ankle (n = 153).

A

FIG 2 • Chopart amputation has a poor reputation because many patients develop an equinus contracture. With transfer of the tibialis anterior to the neck of the talus, this problem can be avoided. This case is an example of synovial sarcoma involving the forefoot. A. This patient’s radiographs showed radiodensity surrounding the second metatarsal, a typical radiographic appearance of a synovial sarcoma. B,C. MRI shows extensive soft tissue mass. The patient was treated with a Chopart amputation. (continued)
FIG 2 • (continued) D. Postoperative photograph shows good dorsiflexion function. E. Chopart amputation can be successful with the transfer of the tibialis anterior into the talar neck. This patient also had a bupivacaine catheter placed for postoperative pain control (A).

FIG 3 • Chondrosarcoma can spread to involve multiple sites. This photograph shows the pathology specimen after a below knee amputation of a chondrosarcoma involving multiple small bones of the foot.

FIG 4 • Chondrosarcoma of the calcaneus. A,B. MRI shows extension into the soft tissue. It was treated with cryosurgery but recurred, and a below-knee amputation was performed. C,D. UCB of the calcaneus. The radiograph shows the typical expansile appearance of the UCB. The CT scan shows greater bony detail. The lesion was treated with curettage, graft, and polymethylmethacrylate.
should be contoured to a rounded end. In a Chopart amputation, the talus and calcaneus should be cut and contoured to fit a prosthesis.

- Myodesis is helpful to pad the end of the stump.
- Reconstruction of the anterior tibialis tendon insertion into the neck of the talus in the Chopart amputation will help prevent an equinus contracture.

**Preoperative Planning**

- Preoperative planning is crucial for a good outcome. The preoperative radiographs and CT and MRI studies are important to determine the amount of tumor involvement. The results of the biopsy will determine the level of amputation.

**Positioning**

- The patient is placed supine on the operating table. A thigh tourniquet is placed over adequate padding, such as Webril. A bump may be placed proximal to the sciatic notch on the ipsilateral hip to limit external rotation of the extremity during the procedure.

**Approach**

- Lisfranc and transmetatarsal amputations are performed through a midfoot incision, with a long plantar flap. This is the same approach with the Chopart amputation. The plantar skin is thicker and has specialized columns of plantar fat to provide for a weight-bearing stump.

**TRANSMETATARSAL AMPUTATION**

- A transverse incision is made either at the middle or proximal third of the metatarsals, extending through skin into the subcutaneous tissue (**TECH FIG 1A,B**).
- The cutaneous branches of the terminal portions of the peroneal nerve are identified. Traction is applied, pulling the nerve distally. The nerve is transected sharply to allow it to retract proximally.
- The terminal branch of the dorsalis pedis is preserved if possible to maintain continuity of the anastomosis with the posterior tibial terminal arterial branch, thus maintaining the dorsalis pedis contribution of arterial flow through the arch.
- The extensor tendons are placed on a stretch, and this is best accomplished by flexing the forefoot and sharply dividing the tendons at the level of the skin incision, allowing the tendons to retract proximally.
- A beveled cut is made in the metatarsal heads by angling an oscillating saw 30 degrees from the perpendicular...
with the foot placed in neutral position on the operating table. A plantar flap is then fashioned by extending the incision through the skin approximately 45 degrees from the transverse dorsal incision obliquely across the medial and lateral foot to the level of approximately the metatarsal heads and then transversely across the skin just proximal to the metatarsal heads.

- The sensory nerve to the first ray is identified, traction is placed, and the nerve is transected sharply. The terminal branches in the medial plantar nerve are identified as well, placed on stretch, and sharply divided. The terminal branches of the medial plantar artery are identified, ligated, and divided.

- The superficial and deep flexor tendons are placed on stretch by dorsiflexing the forefoot through the metatarsal osteotomies and sharply dividing them, allowing them to retract proximally. No attempt is made to suture the extensor tendons to the flexor tendons.

- If there is a significant plantar extension of the tumor, a long plantar flap cannot be used. In this case, a fish-mouth configuration is preferable. To achieve this, equal dorsal and plantar flaps are constructed and the same operation is carried out as indicated above.

- The tourniquet is deflated and meticulous hemostasis is obtained. Excessive use of cautery to obtain hemostasis is discouraged to limit dysvascularity of the plantar flap.

- The plantar flap is brought up and myodesed to the residual metatarsals or tarsal bones. Alternatively, the plantar fascia can be sewn into the periosteum overlying the residual metatarsal heads or capsular structures in and around the tarsal bones.

- The skin is closed with 4-0 nylon sutures. A Penrose drain is placed deep to the flap and brought out either medially or laterally through the incision.

---

**TECH FIG 1 • A,B.** Surgical technique for transmetatarsal amputation. Dorsal and plantar skin incisions. Bone cuts are made with a sagittal saw.

---

**LISFRANC AMPUTATION**

- A transverse incision is made either at the middle or proximal third of the metatarsals, extending through skin into the subcutaneous tissue (TECH FIG 1C,D).

- The cutaneous branches of the terminal portions of the peroneal nerve are identified. Traction is applied, pulling the nerve distally. The nerve is transected sharply to allow it to retract proximally.

- The terminal branch of the dorsalis pedis artery is ligated and divided as it enters the first dorsal interspace and courses in the plantar fascia.

- The extensor tendons are placed on a stretch; this is best accomplished by flexing the forefoot and sharply dividing the tendons at the level of the skin incision, allowing the tendons to retract proximally.
- The Lisfranc joint is disarticulated sharply. A plantar flap is fashioned by extending the incision through the skin approximately 45 degrees from the transverse dorsal incision obliquely across the medial and lateral foot to the level of the distal metatarsals.
- The sensory nerve to the first ray is identified, traction is placed, and the nerve is transected sharply. The terminal branches in the medial plantar nerve are identified, placed on stretch, and sharply divided.
- The terminal branches of the medial plantar artery are identified, ligated, and divided. The superficial and deep flexor tendons are placed on stretch by dorsiflexing the forefoot through the Lisfranc joint and sharply dividing them, allowing them to retract proximally. No attempt is made to suture the extensor tendons to the flexor tendons.
- If there is a significant plantar extension of the tumor, a long plantar flap cannot be used. In this case, a fishmouth configuration is preferable. To achieve this, equal dorsal and plantar flaps are constructed and the same operation is carried out as indicated above.
- The tourniquet is deflated and meticulous hemostasis is obtained. Excessive use of cautery to obtain hemostasis is discouraged to limit dysvascularity of the plantar flap.
- The plantar flap is brought up and myodesed to the tarsal bones. Alternatively, the plantar fascia can be sewn into the periosteum overlying the capsular structures in and around the tarsal bones. The skin is closed with 4-0 nylon sutures, and a small drain is placed deep to the flap and brought out either medially or laterally through the incision.

**TECH FIG 1 • C,D. Surgical technique for Lisfranc amputation. Skin incisions on the dorsal and plantar aspects of the foot. The plantar skin flap is longer. Dissection and removal of the metatarsals. Wound closure with sutures.**

**CHOPART AMPUTATION**

- The Chopart amputation is performed through a transverse incision that is dorsally based at or just distal to the talonavicular joint (**TECH FIG 1E,F**).
- The dorsalis pedis artery and accompanying nerve are identified. The dorsalis pedis artery is ligated and divided, and the sensory nerve is placed on stretch and transected sharply, allowing it to retract proximally.
- The capsule of the talonavicular joint is circumferentially divided, along with release of the posterior tibial tendon. This tendon is tagged for later use as it is brought

**TECH FIG 1 • E,F. Surgical technique for Chopart amputation. Skin incisions with dorsal and plantar flaps. Dissection and removal of bones. Attachment of tibialis anterior tendon into the neck of the talus through drill holes. Wound closure with sutures.**
through the interosseous membrane and reattached to
the neck of the talus with suture anchors or through a
hole drilled in the talus as described above.

- An alternative solution is to place the posterior tibial
tendon through the interosseous membrane with the
medial half of the Achilles tendon. The Achilles tendon is
then suture-anchored to the neck of the talus and used
to augment the tibialis anterior or posterior tibial ten-
don. Achilles lengthening is also a helpful technique be-
cause it reduces the stress on the tibialis anterior. The
Achilles tendon is not necessary for normal ambulation
due to the lack of forefoot.

- A long plantar flap is preferred, but if the tumor extends
into the plantar base and soft tissues, a fish-mouth inci-
sion is made with equal-length dorsal and plantar flaps.

- To help prevent equinus contracture, the tibialis anterior
is detached from the tarsal navicular with a cuff of soft
tissue, preferably periosteum. A drill hole is made
through the neck and head of the talus in an oblique
fashion from dorsolateral to plantar-medial. The tendon
is then routed through this bone tunnel and sewn to it-
self or soft tissue as it exits through the tunnel. This re-
pair may be augmented with bone anchors placed near
the dorsal opening of the tunnel.

- The residual foot is maintained in maximal dorsiflexion
during this repair. Figure 2E shows the position of the
ankle after the amputation and reconstruction of the
tibialis anterior into the talus. Several additional proce-
dures are required for a functional Chopart amputation.
Contracture prevention is critical and ensured through
transfer of the extensor tendons to the dorsum of the
foot and lengthening of the Achilles tendon.\(^5\)

- The posterior tibial tendon and the flexor hallucis longus
and brevis tendons are divided; the tendons are allowed
to retract proximally unless the posterior tibial tendon is
used to augment the dorsiflexion repair.

- The plantar branch of the posterior tibial artery is lo-
cated, ligated, and divided. The flaps are maintained
with sufficient soft tissue to keep them as thick as possi-
able to prevent devitalization of the skin.

- If the head of the talus is prominent, a portion of this
bone can be removed in a beveled fashion by using an
oscillating saw and angling the blade 30 degrees from
distal proximal to plantar distal. The calcaneocuboid
articulation is generally divided, but if part of the cuboid
can be maintained, this is preferable. Contouring the dis-
tal talus and calcaneus will help to decrease the size of
the stumps, and this will help with prosthetic fitting.

- The repair of the plantar soft tissue to the dorsal soft tis-
sue is tenuous as there is no stout tissue dorsally to anchor
the plantar flap. For this reason, a myodesis is preferred;
it is performed by drilling holes in the distal talus and
residual cuboid and anchoring the plantar fascia to the
dorsal residual bone with 0 nonabsorbable suture. The
subcutaneous tissue is approximated with 3-0 absorbable
sutures and the skin repaired with 4-0 nylon suture.

- The residual foot must be maintained in as much dorsi-
flexion as possible. To help achieve this, a rigid dressing
is applied by binding the residual foot from a proximal-
plantar to distal-dorsal direction and applying gentle but
firm compression on the residual foot. This rigid dressing
is applied and extended up to the proximal leg, main-
taining the residual foot and ankle in a maximally dorsi-
flexed position to protect the repair.

---

**CURETTAGE AND CRYOSURGERY OF THE CALCANEUS**

- A sciatic nerve catheter is used for intraoperative and
postoperative pain control. General anesthesia is used for
the procedure. The patient is placed into the lateral decu-
bitus position with the affected side up. A tourniquet is
placed on the upper thigh. After sterile surgical prepara-
tion and draping, an L-shaped incision is made from the
tip of the fibula posteriorly and anterior to the Achilles
tendon. The incision is parallel to the fibula, extending
distally and making a curve at the border between the
dorsal and plantar skin of the calcaneus laterally.

- The initial skin is incised using the scalpel and dissection
is carried down through the subcutaneous tissue. The
incision and approach are inferior to the peroneal ten-
dons, which remain safely superior to the dorsal fasciocu-
taneous flap. The sural nerve is also more superior and
away from the operative field. The lateral wall of the cal-
caneus is exposed.

- A corticotomy is made using a drill to open the lateral
wall of the calcaneus. The tumor is opened, which allows
for the curettage. Large curettes are used to remove the
obvious tumor material. This is followed by inspecting
and burring the edges of the remaining calcaneal wall.
Once the resection is completed, the cavity is irrigated to
again inspect the cavity for remaining tumor.

- To do the cryosurgery, the tourniquet is inflated to 350
mm Hg. Gelfoam is used to line the skin edges and subcu-
taneous tissue around the wound site. The retractors are
placed over the Gelfoam, and laparoscopic tape sponges
are placed around the skin to cover the skin. The foot is
placed into a basin of warm water to try to keep the foot
warm to prevent any problems that the decreased tem-
perature from the cryosurgery may cause in the unin-
volved portions of the foot. Normal saline is poured into
the tumor cavity. Endocare cryosurgery probes are pre-
pared on the back table. Ice balls are formed and noted at
the tip of each of the probes. Three- and 5-mm probes are
used for the cryosurgery. The cryoprobes are placed into
the tumor cavity and left in to complete a 10-minute cycle.
The skin is monitored for necrosis, and warm saline is used
to keep the skin warm and supple. The cavity is allowed
to thaw and the tourniquet is deflated.

- The reconstruction portion of the procedure consists of
an allograft cancellous bone block from the bone tissue
bank that is cut and contoured and placed against the
subchondral surface adjacent to the subtalar joint.
Two small Rush rods are cut, contoured, and placed
within the calcaneus to extend from the subtalar joint,
abutting and holding the allograft in place. PMMA is
mixed with 1 g vancomycin on the back table and prepared by hand mixing. This is placed into the tumor cavity to fill the cavity, completing the reconstruction. The midfoot and forefoot are taken through gentle range of motion to ensure normal movement of these joints and to make sure that there was no iatrogenic extrusion of cement, which could compromise the motion of these joints. Also, the calcaneus is gently axially loaded with hand pressure to ensure that the reconstructed calcaneus moves as a single unit. A drain is placed, and the wound is closed in layers. A plaster splint is used.

SYMES AMPUTATION

- The incision extends from the anterior aspect of the lateral malleolus to the anterior aspect of the medial malleolus, continuing to the plantar skin. The incision at the plantar flap is made to the level of the calcaneocuboid joint. The soft tissues, including tendons, are incised and allowed to retract; the neurovascular bundle is identified and ligated. The talus and calcaneus are dissected sharply and removed.
- The surgeon must be cautious at the point of the Achilles tendon insertion site: the skin is thin and adherent and must be protected.
- The flares of the malleoli are removed with a sagittal saw. The plantar fat pad is fixed to the end of the stump with nonabsorbable sutures into drill holes of the distal tibia and fibula.
- A drain is placed and the wound closed in layers; 3-0 nylon suture is used to repair the skin. A well-padded soft dressing is applied.

PEARLS AND PITFALLS

</table>

POSTOPERATIVE CARE

- Postoperative pain control will allow early mobilization of the patient. Wound healing without complications and prevention of contractures, particularly equinus contractures, are vital.¹
- For the Lisfranc and transmetatarsal amputations, a rigid postoperative dressing is used. The wound is dressed with nonadherent dressing gauze. A gauze roll is used to bind the residual foot. Cotton padding is then placed in strips from the hindfoot to the forefoot from plantar to dorsal in an attempt to reduce the tension on the suture line. The heel is well padded with cotton padding, and then a plaster cast is applied. The cotton padding may have elastic in it for built-in stretch. The plaster is also applied from proximal and plantar to distal and dorsal to reduce the tension on the suture line. The plaster application should be firm but not tight. It should be placed in closed-toe fashion and should extend up to the proximal leg, maintaining the residual foot in the neutral position to a slightly dorsiflexed position. ²
- This initial dressing is changed after 3 to 5 days and the Penrose drain is removed with the first dressing change. A similar plaster is applied for an additional 2 weeks. At the time of plaster removal, the sutures are removed. The patient is given a prescription for a shoe filler.
- After 2.5 weeks, the patient’s foot is placed in a buckle-wedge shoe for an additional 3 to 4 weeks. After that, shoe wear and progressive ambulation are encouraged.
- After a Chopart amputation, the cast is removed after 5 days and the drain is removed. A second dressing and cast are applied for about 3 weeks. The second cast is removed and the sutures are removed at the end of the 3 weeks. A third cast is applied and maintained for 6 to 8 weeks. After the final cast is removed, the patient begins physical therapy to begin range of motion, in particular dorsiflexion and plantarflexion excursion of the residual foot. A prosthetic measurement is taken.

OUTCOMES

- Patients with a Lisfranc, transmetatarsal, or Chopart amputation have good overall function compared with patients with a Syme amputation.³⁴ However, patients with an equinus contracture after a Chopart amputation have inferior results.⁵⁶ A Chopart amputation in a young patient is inferior in function to a Syme amputation due to the lack of ability to replace forefoot function when the space between the floor
and the plantar surface is reduced significantly in a Chopart amputation.

- The Chopart procedure provides an excellent level of amputation for a patient with limited activities and goals. The main advantage to this level is that little is lost between the distal end of the residual limb and the floor. This allows ease of ambulation without the need for a prosthetic device. For persons requiring short trips to the bathroom in the middle of the night or stability for transfers, the Chopart level is perfect. Unfortunately, the lack of anatomic structure and minimal distance from the plantar surface to the floor makes the Chopart amputation a poor choice for the active amputee.

- Ambulation is achieved with a foot spacer. For the Chopart stump, a clamshell type of prosthesis allows good weight-bearing function and restores the effective foot length. Generally, patients are able to ambulate 3 months after amputation using a simple shoe prosthesis.

- Gait analysis shows that abnormality and asymmetry of ground-reaction forces were less with a greater preserved stump length.

**COMPLICATIONS**

- Wound healing complications are treated with local wound care, elevation, and non-weight bearing. Oral antibiotics may be indicated. If there is skin flap necrosis, debridement with a skin graft may be necessary.

- Superficial infection is often resolved with a short course of oral antibiotics.

- Deep infection may require immediate operative débridement of devitalized tissue. Parenteral antibiotics are important to treat this limb-threatening problem. At the time of the débridement, a bone culture should be ordered to help determine the appropriate antibiotic.

- Equinus contracture is most easily treated by prevention. However, stretching with a therapist may be helpful. Serial casting may be required to correct the deformity.

Anatomy and Surgical Approaches of the Forearm, Wrist, and Hand

Asif M. Ilyas, Neal C. Chen, and Chaitanya S. Mudgal

Chapter 1

Unique to the hand, wrist, and forearm is the complex relationship of not only the muscles overlying bone but also the close proximity and delicate balance of accessory anatomic structures, including tendons, vessels, and nerves.

ANATOMY

The anatomy of the hand, wrist, and forearm is intricate and can be discussed in many ways and in extensive detail. For the discussion in this chapter, anatomy will focus on the compartments of the hand and forearm, and their relevance to surgical approaches (Table 1).

DEFINITION

Safe surgical dissection and exposure require an in-depth knowledge of anatomy. In no place is this more relevant than in the surgical approaches to the hand, wrist, and forearm.

The critical aspect of successful surgical approaches is the use of internervous planes.

These planes lie between muscles that are innervated by different nerves.

This allows extensive mobilization and exposure without risk of muscle denervation.
Surgical Management
- All surgical approaches to the hand, wrist, and forearm warrant sound understanding of surface and deep anatomy, internervous planes, and surgical technique.
- Planning the surgical approach begins by identifying reliable surface anatomy.

Preoperative Planning
- Arrangements for instruments, sutures, microscope, imaging support, implants, and assistants should be made before the day of surgery.
- Anatomy, radiographic templating, surgical approach, procedure, and alternatives should be reviewed.

Positioning
- Most approaches to the hand, wrist, and forearm can be performed with the patient supine and the operative extremity extended on a hand table and the surgeon and assistants seated.
- The hand table should be stable and well secured and should allow adequate space for both the operative limb and the surgeon’s elbow and forearm to minimize fatigue and enhance stability.
- The stool should be stable and comfortable, with the height set such that the knees are level with the hips and the feet are resting flat on the ground.
- The lights should be angled directly over the hand table, and not from behind the surgeon or assistant’s shoulder, to prevent shadows on the operative field.
- The use of a pneumatic tourniquet is advised to maintain a bloodless field and clear visualization of all anatomic structures.

Approach
- Multiple approaches to the hand, wrist, and forearm exist and are best divided into the anatomic site and direction of exposure.
- The approach should be chosen based on the indication for surgery.

Skin Incisions of the Hand
- Incisions in the hand can be placed almost anywhere as long as certain principles are respected.
- Incisions should be outlined by sterile surgical markers before making the actual incision to confirm appropriate position, to confirm the adequacy of skin bridges should multiple incisions be used, and to help guide closure.
- Incisions can be made in skin creases on the volar aspect of the hand but incisions in deep creases should be avoided due to the thin subcutaneous tissue, tendency for maceration due to moisture, and tendency toward poor apposition of skin edges on closure.
- Incisions perpendicular to a volar flexion crease should be avoided to prevent scar formation and secondary skin contractures that can lead to loss of motion and functional impairment (TECH FIG 1A,B).
- Incisions on the dorsal surface of the hand can be smaller due to the more mobile and loose nature of the dorsal skin (TECH FIG 1C).

TECH FIG 1 • Examples of volar (A,B) and dorsal (C) incisions for the hand and digits.
Vertical, horizontal, and curved incisions can all be used with good facility as long as adequate skin bridges are maintained. 
- Fingers can be exposed dorsally, volarly, or midaxially. 
- Dorsal incisions can be longitudinal or curvilinear. 
- Volar incisions are best facilitated by a zigzag pattern that crosses creases laterally and at angles. 
- Midaxial incisions are best placed at the junction of glabrous and nonglabrous skin, with attention being paid to the neurovascular bundle that sits in the plane of the flexor sheath. The neurovascular bundle can be taken volarly with the volar flap or can be left in place by carrying the dissection superficial to it.

**APPROACH TO THE INTERPHALANGEAL JOINTS**

- Straight dorsal longitudinal incisions can be made or a variety of curved incisions can be used, including an S-type and a chevron style (TECH FIG 2A).
- In the distal interphalangeal joint, caution must be paid to the germinal matrix, which is about 1 mm distal to the attachment of the extensor tendon.
- At the proximal interphalangeal joint, there is no internervous plane and the extensor mechanism should be immediately evident (TECH FIG 2B).
- The integrity of the central slip inserting in the middle phalanx guides exposure of the proximal interphalangeal joint.
- Three techniques can be employed to approach the joint: 
  - The lateral bands can be freed and gently retracted dorsally, allowing a lateral approach into the joint. 
  - When more exposure is required, the lateral bands can be incised in line with the extensor mechanism and repaired later. 
  - Lastly, to maximize exposure of the joint, the extensor mechanism is cut dorsally in a long distally based V-shaped flap, raised, and later repaired. 
- It is critical not to detach the central slip distally and to maintain continuity of the extensor mechanism through the lateral bands on each side (TECH FIG 2C).

**APPROACH TO THE METACARPOPHALANGEAL JOINT**

- With the metacarpophalangeal joint flexed, identify the apex of the joint, which is the metacarpal head, and the extensor tendon. 
- Make a straight dorsal longitudinal incision centered over the metacarpophalangeal joint. 
- If multiple joints are being approached, a transverse incision centered dorsally connecting each of the joints may be used (TECH FIG 3A). 
- There is no internervous plane. The extensor mechanism should be immediately evident. Sensory branches of

Chapter 1 ANATOMY AND SURGICAL APPROACHES OF THE FOREARM, WRIST, AND HAND

**APPROACH TO THE CARPAL TUNNEL**

- The carpal tunnel is an enclosed fibro-osseous tunnel that contains nine flexor tendons and the median nerve. Its borders include the transverse carpal ligament (the roof), the carpal bones (the floor), the hook of hamate (ulnar wall), and the scaphoid (radial wall).
  - The proximal extent of the tunnel lies at the level of the distal wrist crease.
- Identify the interthenar depression, which lies between the thenar eminence radially and the hypothenar eminence ulnarily (TECH FIG 5A).
- Palpate the hook of hamate and pisiform bone along the ulnar base of the hand.
- Determine the cardinal line of Kaplan, the estimated distal extent of the transverse carpal ligament.\(^4\) The cardinal line of Kaplan runs from the base of the first web space (with the thumb abducted in the plane of the palm) parallel to the proximal palmar crease toward the hook of hamate.
- Multiple incisions can be used depending on the surgeon’s preference, ranging from a limited approach (TECH FIG 5B) to an extensile one.
  - The incision should be centered within the interthenar depression and in line with the third web space to avoid injury to the palmar cutaneous branches of the median and ulnar nerves.\(^8\)
  - The internervous plane occurs between the palmar cutaneous branches of the ulnar and median nerves.
- Incise the subcutaneous fat in line with the skin incision. Deep to the fat lies the longitudinally oriented superficial palmar fascia (TECH FIG 5C).
  - Incise this fascia in line with the incision.
  - Avoid raising flaps radially or ulnarily to prevent skin devitalization and injury to branches of the palmar cutaneous branch of the median and ulnar nerves.
  - Deep to the superficial palmar fascia lies the thick transverse carpal ligament.
  - Release this ligament in line with the skin incision, paying attention to the median nerve lying deep to it as well as being cautious of the recurrent motor branch of the median nerve, which could cross through or across the transverse carpal ligament (TECH FIG 5D).
  - Distal to the transverse carpal ligament, confirm release of the ligament both proximally and distally.
    - Distal release is confirmed on visualization of the “sentinel” pad of fat, which has a distinct yellow color different from that of the subcutaneous fat.
    - Proximal release is confirmed both visually and by feel and usually corresponds to the confluence of the transverse carpal ligament with the deep forearm fascia, generally located at the level of the distal wrist crease.

**TECH FIG 5** • **A.** Surface anatomy of the volar hand. A, radial artery; B, flexor carpi radialis tendon; C, flexor carpi ulnaris tendon; D, pisiform; E, hook of hamate; F, distal pole of scaphoid; G, cardinal line of Kaplan. **B.** Incision for the limited incision carpal tunnel approach. **C.** Superficial palmar fascia of the hand. **D.** Partial release of the transverse carpal ligament with the median nerve lying deep to it. A, retracted superficial palmar fascia; B, partially released transverse carpal ligament; C, median nerve.
PROXIMAL RELEASE IS CONFIRMED BOTH VISUALLY AND BY FEEL AND USUALLY CORRESPONDS TO THE CONFLUENCE OF THE TRANSVERSE CARPAL LIGAMENT WITH THE DEEP FOREARM FASCIA, GENERALLY LOCATED AT THE LEVEL OF THE DISTAL WRIST CREASE.

APPROACH TO CANAL OF GUYON

- The canal of Guyon is an enclosed fibro-osseous space at the ulnar base of the hand through which the ulnar neurovascular structures travel before innervating and perfusing the intrinsic structures of the hand.
  - Its borders include the volar carpal ligament (the roof), the transverse carpal ligament (the floor), the pisiform (ulnar wall), and the hook of hamate (radial wall).
- Palpate the pisiform bone, which lies subcutaneously at the ulnar base of the hand immediately distal to the wrist flexion crease in line with the flexor carpi ulnaris (see TECH FIG 5A).
- Palpate the hook of hamate, which lies about 2 cm distal and 2 cm radial to the pisiform bone.
  - This may be difficult to palpate in patients with large hands or those with well-developed hypothenar musculature.
- Palpate the flexor carpi ulnaris tendon, which runs along the ulnar aspect of the forearm and inserts into the pisiform upon crossing the wrist flexion crease.
- Make a zigzag or curved incision between the pisiform and hook of hamate and extend it proximally (TECH FIG 6A).
- Avoid crossing the wrist flexion crease perpendicularly. Extend it proximally along the radial border of the flexor carpi ulnaris tendon (TECH FIG 6B).
- Identify the flexor carpi ulnaris proximal to the wrist flexion crease and mobilize it ulnarily by releasing the fascia along its radial border. The ulnar artery and nerve will lie just deep and radial to the tendon, with the nerve more superficial and ulnar to the artery.
- Follow the ulnar artery and nerve distally into the hand.
  - In the hand, the flexor carpi ulnaris tendon will insert into the pisiform and the ulnar artery and nerve will dive deep to the volar carpal ligament.
- Releasing the volar carpal ligament radial to the pisiform opens the roof of the canal of Guyon and decompresses the ulnar artery and nerve. In the canal of Guyon, the nerve splits into its motor and sensory branches. The motor branch of the ulnar nerve dives below a fibrous arch formed by the hypothenar musculature originating from the hook of hamate (TECH FIG 6C).
- There is a high frequency of anatomic variations of the ulnar neurovascular structures within the canal of Guyon, and a release of the canal must include not only the roof but also the distal extent of it as it enters below the fibrous arch below the hypothenar muscles.5

TECH FIG 6 • A. Surface anatomy and incision for the approach to the canal of Guyon. A, pisiform; B, hook of hamate. B. The ulnar neurovascular structures in the base of the hand after release of the volar carpal ligament. A, ulnar nerve; B, ulnar artery and vein; C, pisiform with origin of the hypothenar muscles. C. Fibrous arch formed by the hypothenar muscles over the motor branch of the ulnar nerve. A, ulnar nerve; B, sensory branch of ulnar nerve; C, motor branch of ulnar nerve.

VOLAR APPROACH TO THE RADIUS

- Identify the flexor carpi radialis at the wrist flexion crease distally and follow it subcutaneously proximally (TECH FIG 7A).
  - Its tendinous nature will give way to muscle at roughly the middle of the forearm.
- Identify the brachioradialis, which originates along the lateral epicondylar ridge of the distal humerus and is the most superficial muscle mass along the lateral forearm. Distally and laterally it has a broad insertion along the flare of the radial border of the radius.
- Identify the biceps tendon, which is the broad and taut extension of the biceps tendon that crosses anterior to the elbow joint and dives toward its insertion into the radius medial to the brachioradialis.
Identify the radial artery at the wrist. It is found between the flexor carpi radialis and brachioradialis tendons.

With the forearm supinated, begin the incision proximal to the wrist flexion crease and immediately radial to the flexor carpi radialis tendon and extend the incision proximally parallel to the tendon.

The incision can end lateral to the biceps tendon and distal to the elbow flexion crease.

The incision can be extended as shown by the dotted extensions in Techniques Figure 7A.

The length of the incision depends on the extent of bone that needs to be exposed.

As described by Henry, the internervous plane distally occurs between the flexor carpi radialis (median nerve) and the brachioradialis (radial nerve). Proximally it occurs between the pronator teres (median nerve) and the brachioradialis (radial nerve).

Distally the interval between the flexor carpi radialis and the brachioradialis is developed (TECH FIG 7B).

The radial artery lies just ulnar to the brachioradialis tendon and lies underneath the brachioradialis in the middle of the forearm. Dissection should not drift ulnar to the flexor carpi radialis, for the median nerve lies just deep and ulnar to this tendon.

The superficial radial sensory nerve exits from under the brachioradialis at the middle of the forearm, about 8 to 10 cm proximal to the radial styloid, and travels adjacent to the tendon distally. The nerve arborizes proximal to the wrist joint.

Proximally the interval between the pronator teres and brachioradialis is developed.

An alternative to the volar approach of Henry is the trans–flexor carpi radialis approach.

In this approach, the incision is placed directly over the flexor carpi radialis tendon.

The flexor carpi radialis sheath is opened sharply in line with the tendon.

The tendon is retracted ulnarly and the floor of the tendon sheath is opened sharply, leading directly into the deep layer between the finger flexors and the pronator quadratus, also known as the space of Parona.

Several muscles lie over the radius in the deep layer. Distally, the pronator quadratus and flexor pollicis longus cover the radius (TECH FIG 7C). On the middle third of the radius lie the flexor carpi radialis and pronator teres.

To expose the radius, these muscles are released along the volar radial aspect of the radius and are raised in a subperiosteal fashion ulnarly.

Proximally, the supinator muscle covers the radius. Through its substance travels the posterior interosseous nerve as it travels to the dorsal compartment of the forearm.

To expose the radius proximally, the forearm must be fully supinated and the supinator is released along the ulnar border of the radius and raised radially. The forearm must be kept fully supinated to protect the posterior interosseous nerve.

**DORSAL APPROACH TO THE RADIUS**

Identify the tubercle of Lister at the distal and radial aspect of the radius. It is the most prominent bony protuberance on the dorsal distal radius, and the extensor pollicis longus tendon curves around it (TECH FIG 8A).

Identify the “mobile wad of three,” which is the common muscle mass composed of the brachioradialis and the extensor carpi radialis longus and brevis.

Identify the lateral epicondyle of the distal humerus, which is the bony prominence most easily palpable proximal to the radial head along the lateral aspect of the elbow.

With the forearm pronated, make the incision from the tubercle of Lister and extend it proximally along the medial border of the “mobile wad” toward the lateral epicondyle.
The length of the incision depends on the extent of bone that needs to be exposed (TECH FIG 8A).

As described by Thompson, the internervous plane distally occurs between the extensor carpi radialis brevis (radial nerve, posterior interosseous nerve, or both) and the extensor pollicis longus (posterior interosseous nerve).^7^ Proximally it occurs between the extensor carpi radialis brevis (radial nerve; inconsistent innervation) and the extensor digitorum communis (posterior interosseous nerve).

Distally, develop the interval between the extensor carpi radialis brevis and the extensor pollicis longus with the tubercle of Lister positioned between them (TECH FIG 8B).

Exposing proximally, the interval between the extensor carpi radialis brevis and the extensor digitorum communis is identified by the emergence of the outcropping abductor pollicis longus and the extensor pollicis brevis (TECH FIG 8C).

Distally the radius sits immediately below the superficial extensor tendons.

To expose the distal radius, the extensor retinaculum and the sheath of the extensor pollicis longus tendon is opened and the tendon is retracted radially.

The floor of the tendon sheath is incised longitudinally and the extensor tendons are raised subperiosteally, with the extensor carpi radialis longus and brevis taken radially and the finger extensors taken ulnarly.

Proximally, the abductor pollicis longus and extensor pollicis brevis cover the middle third of the radius.

To expose the radius, these muscles are released along their radial border, to avoid denervation, and raised ulnarly.

The proximal third of the radius is covered by the supinator. Within its substance and between its two heads runs the posterior interosseous nerve.

Exposure of the dorsal radius proximally requires exposure and protection of this nerve before elevating the supinator off the radius.

First, identify the nerve as it exits between the two heads of the supinator.

Follow the nerve proximally through the substance of the supinator’s superficial head while taking care to preserve all its branches.

Once the nerve is identified along its entire course, the supinator can be released along its radial border and raised ulnarly.

Musculature of the dorsal forearm. A, extensor digitorum communis; B, extensor carpi radialis brevis; C, abductor pollicis longus and extensor pollicis brevis.

**APPROACH TO THE ULNA**

- Identify the ulnar head and styloid distally with the forearm in neutral rotation (TECH FIG 9).
- Identify the subcutaneous border of the ulna.
- Identify the tip of the olecranon proximally.
- With the forearm in neutral rotation, begin the incision at the level of the head of the ulna but proximal to the styloid. Extend the incision across the subcutaneous border of the ulna proximally toward the olecranon. The length of incision depends on the extent of the bone that needs to be exposed.

Distally, the internervous plane occurs between the flexor carpi ulnaris (ulnar nerve) and the extensor carpi ulnaris (posterior interosseous nerve).

Proximally, at the level of the olecranon, the internervous plan occurs for a short length between the flexor carpi ulnaris (ulnar nerve) and the anconeus (radial nerve).
